NEW AND IMPROVED EDITION.

CHAMBERS'S

INFORMATION FOR THE PEOPLE.

EDITED BY

WILLIAM AND ROBERT CHAMBERS.

VOLUME I.

PHILADELPHIA:
J. B. LIPPINCOTT & CO.
1860.

Walter S. Burke.

PREFACE

After the lapse of eight years since the completion of the *third* and improved edition of the Information for the People, it has become necessary, from the constant and rapid advance of every branch of Science and Art, that the work should undergo a further revision. The various treatises and articles have accordingly been recast, so as to be adapted as nearly as possible to the present state of human knowledge.

Designed in an especial manner for the People, though adapted for all classes, the work will be found to comprise those subjects on which information is of the most importance; such as the more interesting branches of science—physical, mathematical, and moral; natural history, political history, geography, and literature; together with a few miscellaneous papers, which seem to be called for by peculiar circumstances affecting the British people. Thus everything is given that is requisite for a *generally well-informed man* in the less highly educated portions of society, and nothing omitted appertaining to intellectual cultivation, excepting subjects of professional or local interest. It will be understood, then, that the Information for the People is not an encyclopædia, in the comprehensive meaning of the word, but rather one embracing only the more important departments of general knowledge. The ruling object, indeed, has been to afford the means of *self-education*, and to introduce into the mind, thus liberated and expanded, a craving after still further advancement.

It may well be said of the present edition, as was said of the last, that the improvements are very considerable. The scientific treatises have, in general, been carefully remodelled, with due attention to recent discoveries. Subjects, the interest of which is past, have been omitted or greatly condensed, and others of a more enduring and important nature have taken their place. In the Indexes will be found an explanation of, or reference to, almost every subject necessary in ordinary circumstances to be known.

In one important respect—that of the pictorial illustrations and embellishments—it must be obvious, to the most cursory observation, that a very great improvement has been effected.

W. & R. C.

Edinburgh, *October* 1857.

ASTRONOMY.

ASTRONOMY teaches whatever is known of the heavenly bodies. The earth itself it regards only as one of them; viewing it, not in small portions, as we are accustomed to see it, but as an entire body, such as it would appear were we to behold it from a sufficient distance.

The subject falls naturally under two general heads:—1*st*, A *description* of the heavenly bodies—the aspect of the heavens as a whole; the distances, shapes, and magnitudes of the several bodies; the figures they describe in their motions; the way in which they are grouped into systems, &c. 2*d*, Mechanical or Physical Astronomy, or the nature of the powers or forces that carry on the heavenly motions, the laws that they observe, and the calculation of the motions from a knowledge of these laws.

GENERAL APPEARANCES OF THE HEAVENS.

When we raise our view to the sky over our heads, we find it occupied with the sun by day, and the moon and stars by night. The sun is evidently never at rest, but is either ascending upwards in the sky from the east, or else sinking towards the horizon or sky-line in the west, where his body goes out of sight. The same continual motion of rising and setting is observed in the moon; and when the stars are closely watched for any length of time, it is found that they also are constantly in a movement of the same kind. If, at the beginning of a winter-night, we fix our attention on a conspicuous star near the east point of the horizon, and continue to observe it, we shall see it rising higher and higher for about six hours; it will then begin to descend to the west, and in about six hours more it will reach the west point of the horizon, and disappear. If we commence our watch again on the following night, we may discover the same star rising at the east point at about the same hour, and going through its course of mounting, crossing, and descending the sky as before.

If we turn to some point between east and north, and notice a star just rising, we find it gradually ascending in the heavens up to a certain point; then descending to the west, and going out of sight; and finally reappearing in the east in about twenty-four hours from the time of its previous rising: but these twenty-four hours, instead of being spent one half above and the other half below the horizon, as in the former case, will be unequally divided between the presence and the absence of the star; more than twelve hours will be taken to pass from the rising to the setting, and less than twelve hours will elapse between the setting and the next rising. The further *north* the point of rising, the longer the time spent in the upper course, and the shorter the time in the under and unseen course. If we go to the north point itself, and observe a star just a little above the horizon, we shall find that it will spend the first twelve hours in ascending to its highest point in the heavens, and the next twelve in descending to the neighbourhood of the horizon; and it will not go beneath at all, but commence again to rise and describe a circle in the heavens as before; such a star, therefore, will be always in sight. In like manner, all stars in the north quarter lying within the circle described by this never-setting star, will perform their daily movement above the horizon.*

Poles, Axis.—In the inside of these circling motions we may observe a point in the sky which seems to be their common centre. A star lying in it would be perfectly at rest, and stars near it describe very small circles, or move within narrow limits. This point of rest is situated in the north quarter of the heavens, but more than half-way up from the sky-line, towards the summit. It is called the *north celestial pole*, or the *north pole of the heavens*, and is the most important point in the sky for astronomical references. No visible star is actually residing in it; but a very bright star lies near it, called for that reason the *pole-star*.

By observing the movements of stars that rise in the *south-east*, and seeing their visible paths becoming

* In the foregoing and in succeeding paragraphs, it is supposed that the stars may be seen day and night. By the naked eye no star can be seen while the sun is up, but they are all in their places nevertheless. The intense light of the sun generally makes other celestial objects invisible. With good telescopes, however, the stars may be seen in the daytime, in a clear day, except in the sun's immediate neighbourhood. From the bottom of deep wells and mines the stars in the sky overhead are seen through the day. When the moon is at a considerable distance from the sun, it may be seen when the sun is up.

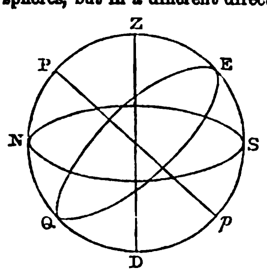
shorter and shorter, as they lie more southward, we cannot help inferring that there is a large region of stars describing circles wholly out of sight, and that there is a point beneath, which is the centre of these circles, corresponding to the centre of the northern heavens. This point is called the *south celestial pole*. An imaginary line drawn from pole to pole, or from the elevated north resting-point to the concealed south resting-point, is called the *axis of the heavens*, or the *axis of the world*. Owing to one pole being a considerable way up in the sky, and the other far down out of sight, it is evident that the great whirl of the starry sphere goes on in a *slanting* direction.

Besides the poles and axis of the heavens, there are many other imaginary points, lines, and circles, which it is convenient to suppose drawn among the stars, and which of course we can actually draw in all figures and sketches of the starry heavens. The most important of these may be here explained.

Equator, Horizon, Zenith, Meridian.—The celestial *equator*, so called because it cuts the starry sphere into two equal halves, is an imaginary circle passing round the heavens midway between the two poles. The two halves into which it divides the sphere of stars form the *northern and southern hemispheres*.

The *horizon*, or the line where the earth seems to meet the sky, makes another division of the starry sphere, into the visible hemisphere, or stars *above the horizon;* and the invisible, or stars *below the horizon.* The point of the heavens directly over our heads, or the very summit of our sky, is called the *zenith*. It is a sort of pole, or middle point, of the visible half of the heavens. The point that we should see directly beneath our feet, if the earth could be seen through, is called the *nadir*, and forms a pole and a middle point to the nether half of the heavens. These are Arabic words, meaning the extreme up and the extreme down points.

Another artificial circle supposed to be drawn in the heavens, is the *meridian*. Like the equator and the horizon, it divides the starry sphere into two equal half-spheres, but in a different direction from either of those circles. In fact, it is so drawn as to be perpendicular to both. It passes through the north point of the horizon, then upward through the north celestial pole, through the zenith, down through the south point of the horizon, through the south celestial pole beneath, and finally through the nadir: so that, in the first place, it lies north and south; and in the second place, it stands upright. Thus, if in the figure, Pp be the great axis of the heavens terminating in the north and south celestial poles, EQ the celestial equator, NS the horizon, and N and S the north and south points of it, Z the zenith, and D the nadir; then the enclosing circle of the figure NPZESpDQ is the meridian.



The leading property of the meridian is, that it determines the greatest height and the lowest depth that any star can reach. Hence when the sun or the moon passes the meridian, or lies due south, we know that it has reached its greatest height, and will immediately commence to descend. Hence, also, we can determine the meridian line in the heavens, by observing where a star is when it ceases to ascend and begins to descend; which of course gives us the direction of the north and south points, and serves the same end as the mariner's compass. The meridian also divides the upper and lower course of the stars into equal halves. The middle point between a body's rising and setting is its meridian passage.

Fixed Stars and Wanderers.—Although the general starry sphere turns round in one great mass, so that each star is always in the same place among the other stars, it was early observed that there were exceptions to the common movement; and that a small number, besides going round the sky daily, shift about among the others, so as to be sometimes near one, and sometimes near another. In opposition to these erratic or *wandering* bodies, the general multitude that kept their places were called *fixed stars*, and are used as landmarks whereby to trace the motions of the others.

The moon, for example, is soon observed to be an erratic body. One night we see it near one star, and the next night it is at a considerable distance to the east of it; even in a few hours there is a visible change of position. In the course of a month, we find it has gone through a complete circle from west to east among the stars, and come back nearly to the same place.

The sun has a similar motion, though it is slower, and also less easily marked, because his light prevents the stars from being seen at the same time. If we could see a star any night setting at the same instant as the sun, we should find that the next night it would set four minutes *before* the sun, the sun having in the meantime moved backward a short distance.

Ecliptic, Latitude, Longitude, Declination, &c.—When this motion of the sun among the stars is observed for a length of time, it is found that it forms a circuit, bringing him back, in the course of a year, to the same position. The path, however, which he travels is not exactly east and west, or parallel to the equator. If this were the case, the sun would rise and set always in the same points of the horizon. But we see that on the 21st of March, for instance, he rises exactly in the east; for the next three months the point of his rising is more and more north of east, till the 21st of June, when it begins to recede, and again reaches the east point on the 21st of September; and during the winter months it makes a similar approach to and retreat from the south. The amount of divergence either way is about a fourth of the distance between the east point and the north or south point. From this, and other appearances, it is evident that the annual path described by the sun among the stars runs slanting across the equator. This is an important circle in astronomy, and is called the *Ecliptic;* the angle which it makes with the equator is called its *obliquity*, and on this depends the variety of the seasons. Its amount is about a fourth of a quarter circle (23° 28′).

The points where the celestial equator and the ecliptic cross one another are called the equinoctial points, because the sun is in them at the equinoxes. The vernal equinoctial point is used as a fixed mark from which to measure distances on the heavens east and west, just as we measure distances east and west on the earth, or terrestrial longitude, from Greenwich.

The terms *latitude* and *longitude* have different meanings in astronomy and in geography. The latitude of a place on the earth's surface is its distance north or south of the equator; the latitude of a planet or star is its distance from the ecliptic, while its distance from the celestial equator is called *declination*. The longitude of a place is its distance east or west from the first meridian counted along the earth's equator; longitude in the heavens is distance eastward from the point Aries, measured in the direction of the ecliptic, and not in that of the equator. The distance of a heavenly body from Aries, measured in the direction of the celestial equator, is called its *right ascension*. The reason why the ecliptic is chosen to refer the latitudes and longitudes of the heavenly bodies to, is, that it is the only circle in the heavens that approaches to the permanency of the earth's equator; it maintains almost a fixed position among the stars, while the celestial equator shifts its position in the course of ages, and thus divides the starry sphere differently at different periods.

Besides the sun and moon, there are a good many other wandering stars. The ancients discovered five of

these, and gave them the name of *planets*, from the Greek word 'to wander.' The rest have been discovered since the invention of the telescope.

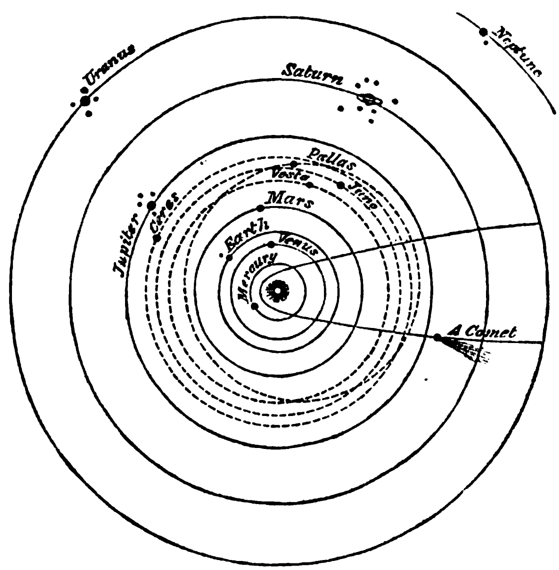
Copernican and Ptolemaic Systems.—We have hitherto spoken of the *appearances* of the heavenly bodies and their motions, without inquiring whether they are as they seem. For long, these apparent motions were considered to be real motions. The earth was believed to be—what it seems to be—a fixed station, the centre of the universe; the starry sphere was a solid shell, revolving daily with its thousand fixed fires round the central earth; while within it were a succession of crystal spheres, carrying the sun, moon, and planets, and, while partaking of the common motion from east to west, having also each a motion of its own. But as observations of the planetary motions were multiplied, it became more and more difficult to account for all the appearances in this way. At last it was found necessary altogether to change the point of view—to give up the earth as the centre of all the heavenly motions, and admit that it itself, along with the other planets, is in motion round the sun as a centre. This view, called the Copernican system, from Copernicus, its author, is now universally prevalent; the earlier is known as the Ptolemaic system, from Ptolemy, the chief ancient writer on the subject whose works we possess.

Instead of attempting to state the arguments by which the old opinions are refuted, we will proceed at once to give an outline of what is now believed to be the arrangement and constitution of the heavenly bodies. The simple way in which the Copernican system accounts for all the appearances, is the best argument in its favour.

THE SOLAR SYSTEM.

Of the heavenly bodies, those spoken of above as wanderers compose a group altogether apart, the earth being one of them. The sun, which is vastly greater than all the rest put together, forms the centre of the group; which is hence called the *solar* system (from *sol*, signifying 'sun'). Though the distances of the bodies of this group, from the central sun and from one another, are enormous when measured by ordinary terrestrial standards, they become as nothing when compared with the space that separates the whole of them from the nearest of the fixed stars. The solar system forms thus a compact inner world, cut off by an almost immeasurable chasm from the outer universe. It is with this inner world that the astronomer has chiefly to do; what is known of the fixed stars will be spoken of apart, under the head of Sidereal Astronomy.

Around the sun as a centre, the smaller bodies or *planets* wheel at different distances in paths or *orbits* of a round form, being what are called ellipses; these



The Solar System, to the orbit of Neptune.

MOON, . .	2,153	0·62	$\frac{1}{28394880}$	*	*	2,265	10

orbits lie pretty nearly in the same plane, a plane passing through the sun's centre; and the motions of the planets are, as a general rule, all in one direction—from west to east.

Some of the planets have other planets moving round them as centres—the moon, for instance, round the earth. These are called *secondary* planets, *moons*, or *satellites;* while those that move round the sun are called *primary* planets. The primary planets now known consist—1*st*, of eight larger planets, including the Earth; their names, in the order of their nearness to the sun, are—Mercury, Venus, the Earth, Mars, Jupiter, Saturn, Herschel or Uranus, and Neptune. 2*d*, A group of small planets or *planetoids*, called sometimes also asteroids, at least forty in number. They are situated between Mars and Jupiter; and their orbits are so close and intimately connected, that the whole may be considered as making only one planet.

The satellites or moons, as yet discovered, number twenty; of which the Earth has one, Jupiter four, Saturn eight, Uranus six, and Neptune one. In addition to its moons, Saturn is attended by a luminous ring.

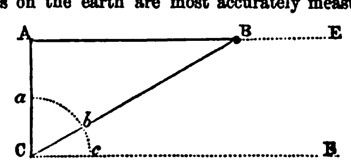
Those singular bodies called *comets* (Lat. *coma*, a lock or brush of hair) also belong, many of them at least, to the solar system. And in addition to the above luminous members of the system, it is now becoming apparent that there are multitudes of dark bodies, of various sizes, circling in the spaces between the known planets, some of which become visible to us when they accidentally enter our atmosphere as *shooting-stars* and *aërolites*.

Such is a brief inventory, as it were, of the furniture of this inner world to which we belong. Some idea may be formed of the comparative sizes and distances of the principal objects composing it, by supposing a globe of two feet diameter, placed in the centre of a level plain, to represent the sun; a grain of mustard-seed, placed on the circumference of a circle 164 feet in diameter, for Mercury; a pea, on a circle of 284 feet, for Venus; another pea, on a circle of 430 feet, for the Earth; a large pin's head, on a circle of 654 feet, for Mars; a number of minute grains of sand, on circles of from 1000 to 1200 feet, for Vesta, Ceres, Pallas, Juno, Astræa, Hebe, Iris, Metis, &c.; a moderate-sized orange, on a circle of nearly half a mile in diameter, for Jupiter; a small orange, on a circle of four-fifths of a mile in diameter, for Saturn; a small plum, on a circle of a mile and a half in diameter, for Uranus; and an ordinary plum, on a circle of two miles and a half, for Neptune. It is calculated that the united mass of the whole of the ascertained planets is not above a 600th part of the mass of the sun.

The figure on the preceding page represents the relative positions of the chief planetary orbits, including those of the four earliest discovered planetoids. Appended are tables of the diameters, distances, and other numerical particulars of the several bodies.

Astronomical Mensuration.—Though it would be inconsistent with the scope of the present sketch to describe minutely the processes by which the above numbers are found, it is necessary to give a general idea of the methods followed, that the reader may be able to conceive the possibility of measuring and weighing objects so completely beyond our reach.

The astronomer finds the distance between objects, not by measuring lines, but by measuring *angles*. Even distances on the earth are most accurately measured in

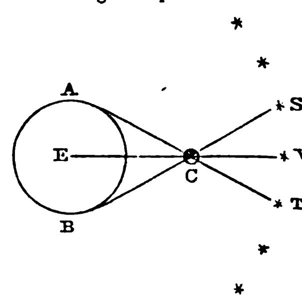


this way, as in trigonometrical surveying. Suppose that an observer at A wishes to ascertain the distance of an inaccessible object at B; it could never be found by looking at it from A alone. He chooses another station, C, to which he has access, in a direction perpendicular to the direction of B, and at a convenient distance, say 100 yards. If the object looked at from A lay directly east, it will no longer be east when looked at from C; its direction is now CB, not CE, and the difference of direction is seen in the greater or less wideness of the opening between those two lines, or in the *angle* BCE, as it is called.

To ascertain the exact comparative wideness or size of angles, a circle is described about the point C, where the lines meet, and the lines intercept a greater or less portion or arc of it. As the circle is supposed divided into 360 equal parts, called degrees, if the arc *cb*, for example, is the twelfth part of the whole circle, it will contain 30°; 30°, therefore, is the measure of the angle BCE, and also of the angle ABC, which, as is evident to sight, is equal to BCE. It is clear, too, that the arc *ac* being the fourth part of the whole circle, and thus containing 90°, the arc *ab*, or the angle ACB, will contain 60°.

By considering the figure, it will be seen that the more distant B is, the larger must be the angle ACB, and the smaller must be ABC. For every size of either of these angles there is a certain fixed length of AB; and trigonometry teaches, from knowing the *base* AC and either of them, to find the length of AB. Everything depends on measuring the angles of direction, or the angular distances, accurately. Degrees are divided each into 60 parts, called *minutes*, and these again into 60 parts, called *seconds;* and astronomical instruments are now so delicate that a difference of direction of one second can be measured.

The difference of direction in which a body is seen when viewed from two places at a distance from one another, is called by astronomers *parallax*, or displacement. The annexed figure represents the effect of parallax on a heavenly body C. V is its *true* place, or place in the sky as seen from the earth's centre; T is its place as seen from the surface at A, and the arc TV, or the angle ACE, is the amount of the horizontal parallax.



The distances of the heavenly bodies, even the nearest of them, are so great, that even when the two stations are taken as wide apart as possible—that is, from the opposite sides of the earth, where the distance between them is equal to the earth's diameter, or nearly 8000 miles—the angle of parallax ACB, or the displacement on the sky TS, is very small. In the case of the moon, the nearest of the heavenly bodies, it is nearly two degrees; and by means of it the distance of the moon is found to be about 237,000 miles, or about sixty times the half-diameter or radius of the earth. When the sun is observed from opposite sides of the earth, he suffers a displacement of only seventeen seconds of a degree. This corresponds to a distance of about 95,000,000 miles. On so small an angle, a slight error of observation materially affects the result; and therefore other expedients were had recourse to, to determine the sun's distance with greater certainty and exactness. When the distance of the earth from the sun was once known, a new and vastly extended base was obtained for the trigonometrical survey of the heavens. As the earth travels in its annual circuit round the sun at the distance of 95,000,000 miles, by observing a heavenly body at two different times, at an interval of

six months, we in effect observe it from two stations removed from each other by the whole breadth of the earth's orbit, or nearly 200,000,000 miles. The displacement produced in this way is called *annual parallax*. Even this enormous base becomes as nothing when applied to measure the distances of the fixed stars; by far the greater number shewing no sensible parallax.

Knowing the distances, we can find the real sizes of bodies from their apparent size, or from their dimensions taken by an angular instrument. If an object be a mile off, and if its breadth make an angle of 1° at that distance, its real size is determined by these two quantities. Thus the *moon* being about 237,000 miles from the earth, and having an angular breadth in the sky of somewhat more than half a degree, its actual breadth must be about 2000 miles. The accurate estimate is 2153 miles—rather more than a fourth of the diameter of the earth. The *sun* has almost the same apparent size in the sky as the moon; but being at about 400 times the distance of the moon, it must have 400 times the breadth of the moon to appear equally large. In fact, the sun's diameter is more than 111 times that of the earth. The diameters of the planets are determined in the same way.

The solid contents or *volumes* of the several bodies are found from their diameters, by a simple rule of geometry. To state the number of cubic miles that each contains, gives little real information, the important thing being their relative magnitudes. Now, it is important to bear in mind that the magnitudes or bulks are not in the simple proportion of the diameters, but as the *cubes* of the diameters. Thus, the diameter of the sun being upwards of 111 times that of the earth, his volume or bulk will be 1,400,000 (111 cubed) times greater.

To speak of *weighing* such stupendous masses as the sun, moon, and stars, seems at first sight extravagant; yet it is by no means one of the most difficult problems, as will be explained under Mechanical Astronomy.

Diameter of the Earth.—In measuring the distances of the heavenly bodies, the diameter of the earth is taken as a known base to start from; but how is this got at? If at any place we observe the height of a star on the meridian—say the pole-star—and after travelling directly north for a considerable distance, observe the height of the same star, it will be found to be greater. This arises from the round form of the earth; and it is easily shewn that if the star has risen one degree higher in the heavens, the observer must have moved north one degree. We are thus enabled to fix two stations on a meridian, the distance between which shall be exactly one degree, or the $\frac{1}{360}$th part of the whole circle or circumference of the earth. When the length of such a line is measured, it is found to be a little less than seventy English miles. This, multiplied by 360, gives the whole circumference in round numbers at 25,000 miles, and the diameter at 8000.

SEPARATE MEMBERS OF THE SYSTEM.

The Sun (☉).—The apparent or angular breadth of the sun is, on an average, 32′ 3″; owing to its being nearer to us at one time than at another, the apparent magnitude varies about half a minute either way. The real diameter of the sun, as already stated, is 111 times that of the earth, and its volume 1,400,000 times as great. It may help to form a vivid conception of this comparative vastness, to conceive the sun a hollow sphere, and the earth placed at the centre; in this position, the moon circling round the earth at the distance of 240,000 miles, would be still 200,000 miles from the circumference of the sphere.

That the sun is a ball or globe is evident from its always appearing round, while we know, at the same time, that it turns or rotates on an axis. The fact of its rotation is inferred from dark *spots* which are seen at times on its surface: they are observed to move all at the same rate, and in the same direction across the surface, to disappear for a time, and then come again into view at the other side; and by this means the period of rotation is ascertained to be 25¼ days.

A careful study of these spots has led to some very probable conjectures as to the nature or physical constitution of the sun. A solar spot presents the appearance of an intensely black irregular patch, surrounded by a less dark fringe. They appear and disappear very irregularly, some lasting only a day, others for weeks and even months. Sometimes no spots are to be seen for a long time, at other times they appear in profusion. But it is observable that they are confined to two broad zones, parallel to the sun's equator, and corresponding in some degree to the temperate zones on the earth. Individual spots have been seen to attain the enormous breadth of 45,000 miles, covering an area of five times the surface of the earth.

Judging from all the appearances, it is held highly probable that the nucleus of the sun is a dark solid globe, and that this is surrounded by two gaseous coatings or layers of some depth, the lower one being non-luminous, like our atmosphere, and the upper being a luminous gas or flame. An opening, then, in this upper luminous stratum, like a break in a layer of clouds, would present the appearance of a dark spot. The openings might be occasioned by any commotion in the gaseous coverings of the sun similar to our tornadoes or hurricanes. As to the source of the sun's *heat*, we can only conjecture. It is difficult to suppose it to be combustion of any kind, and electrical currents have been suggested as the cause.

From appearances attending total eclipses of the sun, and other phenomena, it is concluded that there is a third gaseous atmosphere, above the luminous matter. It is imperfectly transparent and cloudy, and seems to extend many thousand miles in height. The rose-coloured projections seen during eclipses are believed to be clouds in this atmosphere.

Some hold it not improbable that the sun may be inhabited. The gaseous stratum, which is the source of light and heat, appears to be at a great elevation above the solid nucleus; and the non-luminous stratum or atmosphere that intervenes may be of a nature to temper the rays, and render their intensity consistent with organic life.

Mercury (☿) and *Venus* (♀), the two members of the system next to the central body, are called *inferior* planets, from their orbits being within that of the earth. Owing to their position, they can never appear at any great distance or *elongation* from the sun. Mercury, in fact, even at its greatest elongation, sets long before the end of twilight, or if west of the sun, does not rise till the dawn has begun; so that in our latitude and cloudy climate, it is rarely seen with the naked eye. Venus attains more than twice the elongation of Mercury, and is seen long after night has fairly set in, or before the morning twilight. Both inferior planets go through *phases* like the moon, and when seen through a telescope, have a crescent or a gibbous shape. They are never seen when full, or when new, being then near the sun. Venus is the most conspicuous of the heavenly bodies, next to the sun and moon; when it rises before the sun, it is called the *Morning Star*—the Lucifer of the ancients; and when it sets after the sun, it is the *Evening Star* or Hesperus.

Telescopic observations of Mercury and Venus are very difficult, owing to the intense brilliancy of the surface. It is concluded that we do not see the real surface, but only their cloudy atmospheres. Even the times of their rotation on their axis cannot, according to Sir J. Herschel, be held as accurately determined; still less the height of the mountains, which some observers have fancied they saw. Others think it

satisfactorily demonstrated that Venus rotates in 23 hours 15 minutes. The dense clouds which load the atmospheres of those planets, may mitigate the intense glare of the sun, and render them habitable by organised beings.

The *Earth* (⊕) is the third planet in order from the sun, and closely resembles Venus. Its diameter in round numbers is, as already stated, 8000 miles. But the earth is not a perfect sphere; it does not measure the same in all directions, but has its axis, or the diameter on which it rotates, shorter than its diameter at the equator. This is a general law in all planets, the cause of which will be explained under the head of Mechanical Astronomy. The earth, then, is flattened at the poles, and its shape is called by astronomers an oblate spheroid. If it were cut in two, by a plane passing through the two poles, the section would be, not a circle, but an oval, or *ellipse;* and the excess of the *equatorial* diameter over the *polar* diameter is called the *ellipticity* of the spheroid. The ellipticity of the earth is found to be $\frac{1}{300}$, or the equatorial diameter exceeds the polar by $\frac{1}{300}$th of its length.

This was determined in two ways: by measuring degrees of the meridian at different latitudes; and by measuring the variation in the force of gravity, between the equator and the poles. In the ellipse formed by a section of the earth in the direction of a meridian, the curvature or bending is sharper towards the ends, or near the equator, than towards the poles. The ends of the ellipse are portions of a smaller circle, as it were, than the middle parts; and a degree of the smaller circle will be shorter than one of the longer. The lengths of a degree in various latitudes, from the equator, to upwards of 60° north, have been measured with great accuracy, and been found to increase towards the pole, and from these the lengths of the two diameters have been calculated. The polar diameter, omitting fractions, is 7899 miles, the equatorial 7925; the difference is thus 26 miles, and the mean diameter 7912 miles.

The variation of gravity at different places on the earth's surface, as measured by the vibrations of the pendulum (see NATURAL PHILOSOPHY), gives the same results, and thus the two methods confirm one another.

To ascertain the density of the earth, is a delicate problem, to be more particularly described under the head of Mechanical Astronomy. It is found to be from 5½ to 6 times that of water. The densities of the other heavenly bodies are always given as compared with that of the earth, which is stated as 1. The motions of the earth, and the appearances caused by them, as well as the motions of its accompanying satellite, the moon, will be described under separate heads.

Mars (♂), the fourth in order, is the nearest to us of the *superior* planets. Its volume is less than the seventh part of that of the earth, and its mass nearly in the same ratio. By means of spots on its surface, it is distinctly ascertained to turn on its axis in 24 hours 37 minutes, the axis being inclined to the plane of its orbit at an angle of 28° 27′. Its days, then, are nearly the same as ours; and its year, which contains 668 Martial days, is varied by seasons like the terrestrial year. Mars has a reddish aspect; permanent spots and markings are seen by the telescope, which must therefore be on the solid surface. Around each pole is a region of dazzling white, conjectured to be snow, from the circumstance that the white circle is observed to diminish during the summer of the hemisphere in which it lies, and increase during the winter, exactly as the snows of the terrestrial polar regions do.

The *planetoids* or *small planets* circulate in a region lying between the orbits of Mars and Jupiter, but on the whole nearer to the former. They form a distinct group of themselves, and the region of their orbits may be considered as constituting a zone of separation dividing the eight chief planets into two groups—four *interior* planets (Mercury, Venus, the Earth, Mars), and four *exterior* (Jupiter, Saturn, Uranus, Neptune), which two groups present several points of contrast. It is only recently that the existence of the small planets has become known, the first, Ceres, having been discovered in 1801. From observing, however, that there is a sort of law in the distances at which the planets generally succeed one another, it had long been conjectured that a planet or planets might yet be discovered in the interval between Mars and Jupiter, which formed a break, as it were, in the regularity of the progression. The discovery of Ceres by Piazzi at Palermo in Sicily (Jan. 1, 1801), was followed by that of Pallas (March 28, 1802) and Vesta (March 29, 1807), by Olbers, at Bremen, and of Juno (Sept. 1, 1804), by Harding, at Lilienthal, near Bremen. A period of thirty-eight years followed without any addition being made to the group. In the meantime, a multitude of observers had laboured with untiring industry in mapping down the smaller stars in the region of the zodiac, so as to make it more easy to distinguish between a moving body and a fixed. The fruit of these labours began at length to appear in the discovery of Astræa (Dec. 8, 1845), and that of Hebe (July 1, 1847), by Professor Hencke, in Prussia. The observations of Mr Hind, in London, De Gasparis at Naples, and other astronomers, have since raised the number of the asteroids to above forty, with every prospect of further additions.

In addition to their comparative smallness, the planets of this group are distinguished by their orbits being much more elliptical or elongated than those of the others, and also having a greater inclination—that is, rising and sinking much further from the plane of the ecliptic. The inclination of Pallas is as much as 34° 37′. It is difficult to determine the diameters of the telescopic planets with any certainty. The largest is held not to exceed 600 miles in diameter, and the great body of them to be under 100 miles.

The distances of the small planets from the sun mostly range between two and three times that of the earth; and in the case of several of them, the difference of distance is very small. Besides being unusually near to one another, their orbits are singularly interlaced. 'The strongest evidence,' says one astronomer, 'of the intimate connection of the whole group of small planets appears to be, that if the orbits are supposed to be represented materially as hoops, they will hang together in such a manner, that the whole group may be suspended by any given one.' From these and other observed facts, cosmogonists presume that the matter which in other cases has gone to form one planet of the first rank, has in their case been separated into several parts, assuming various but connected orbits. Olbers boldly conjectured that a single primitive planet had, by explosion or other natural force, been shattered to pieces; and an American astronomer, Mr Kirkwood, has undertaken to restore the exploded primitive planet from the fragments, as the animals of the primitive earth are restored from their fossil remains.

Jupiter (♃).—The four planets constituting the *outer* group are on a much more stupendous scale than the inner; hence they are called by some *major* planets; while the inner group are called *terrestrial* planets, from their many analogies to the earth. The first and largest of all is Jupiter. The diameter of Jupiter being upwards of eleven times that of the earth, his volume is 1400 times the volume of the earth. In its orbit this enormous globe moves at the rate of 500 miles a minute—a speed sixty times greater than that of a cannon-ball, and yet it takes nearly twelve of our years to accomplish its circuit! To the inhabitants of Jupiter the sun must appear less than one-fifth of the breadth he presents to us. By means of permanent marks, it is ascertained that the planet rotates on an axis inclined to its orbit at the small angle of 3° 6′, and in the short space of 9 hours 55 minutes. This makes the rotary velocity of Jupiter's

surface twenty-seven times greater than that of the earth. Viewed through a telescope, Jupiter appears traversed by dark lines, or belts, which are supposed to be parts of the body of the planet, seen through openings in a bright cloudy atmosphere.

Jupiter is attended by four satellites, which revolve round it as the moon revolves round the earth, but in much shorter periods—the nearest requiring only forty-two hours. One of these satellites is of the same size as our moon; the others, larger. Their density is very small, one of them being twice as light as cork; so that the mass of the whole is only a 6000th part of that of Jupiter itself. Seen from his first satellite, Jupiter must present a surface more than 300 times greater than that of the full-moon. These satellites frequently eclipse the sun to Jupiter; they are also eclipsed by the primary planet.

The satellites of Jupiter were discovered by Galileo, being among the first results of the invention of the telescope. They have been of great use in several astronomical calculations of importance, particularly in suggesting the theory of the gradual propagation of light. It having been observed that their eclipses always took place sooner than was to be expected when the earth was near Jupiter, and later when it was at the greatest distance, an astronomer solved the difficulty by supposing that light required some time to travel—a conjecture which was afterwards confirmed by other observations.

Saturn (♄) with its ring, or rather rings, and eight moons, is the most remarkable member of the solar system. Its volume is about 900 times that of the earth; but its density being only a little more than half that of water, its mass is 100 times that of the earth. It turns on its axis in 10 hours 29 minutes, and its year is about 29½ of our years.

The singular appendage called the ring of Saturn surrounds the body of the planet in the plane of its equator. It is thin and broad like the rim of a spinning-wheel, and is always seen with its edge presented more or less directly towards us. It is luminous with the sun's light, and casts a shadow on the surface of the planet. The distance of the inner edge from the planet is calculated at about 19,000 miles; its entire breadth from the inner to the outer edge is 29,538; the thickness is about 250 miles. In certain positions of the planet, we can see its surface at a considerable angle, and the openings or loops which it forms at the sides of the planet. At other times, we see its dark side, or only its edge. From observations made upon it in favourable circumstances, it is found to be divided into two independent and concentric rings of unequal breadth, the outer being the smaller. The interval, which appears as a dark line, is about 1800 miles broad. In 1850, a third, feebly luminous and darker ring, was discovered between the planet and what had hitherto been called the inner ring, from which it is separated by a black line. The rings rotate in their common plane in the same time, or nearly so, as the planet, and the centrifugal force thus generated prevents them from collapsing and falling in upon the planet. Some astronomers are of opinion that 'the ring consists of a stream or streams of a fluid rather denser than water flowing round the primary.'

The eight satellites of Saturn revolve around it, on the exterior of the ring, and almost all of them in nearly the same plane. They are so small as not to be visible without a powerful telescope. The revolutions of these satellites range from one to seventy-nine days. The distance of Saturn reduces the light and heat derived directly from the sun to the ninetieth part of their intensity at the earth's surface; on the other hand, the spectacle of the heavens arising from the reflected light of the rings and moons must be magnificent and varied.

Uranus (♅) is invisible to the naked eye, and was discovered by Sir William Herschel in 1781. Its distance from the sun is nineteen times that of the earth, requiring two hours and a half for the sun's light to reach it. Its volume is eighty-two times that of the earth. Its period of rotation is stated at 9 hours 30 minutes; while others hold that nothing is known as to its rotation, or to its atmosphere and surface.

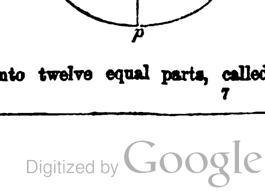
Uranus is attended by at least four satellites, probably by five or six. In two respects, these satellites are quite singular: their orbits are nearly perpendicular to the plane of the ecliptic; and their motions in the orbits are *retrograde*—that is, from east to west, instead of being from west to east, like those of all other planets both primary and secondary.

The discovery of *Neptune* (♆) is one of the greatest triumphs of scientific astronomy. From irregularities observed in the motion of the planet Uranus, it had been conjectured that some disturbing cause, not yet discovered, was acting upon it. Two astronomers, M. Le Verrier, in Paris, and Mr J. C. Adams of Cambridge, independently of one another, calculated where this disturbing cause must be situated. The results of Le Verrier were first made public; and Dr Galle of Berlin detected the new planet at the first search, September 23, 1846, within two diameters of the moon's disk from the place assigned for it by Le Verrier. The distance of Neptune from the sun is thirty times that of the earth. Its year is nearly 165 of ours (60,126·7 days); and it has been ascertained to be attended by at least one satellite, whose orbit is inclined to the ecliptic at the large angle of 34°.

UNIFORMITIES OR LAWS IN THE SOLAR SYSTEM.

These details of the movements, magnitudes, distances, &c., of the separate members of the solar system, are apt at first sight to appear a mass of unconnected facts, without any discernible plan; but more attentively considered, they display in several respects order and law. The regular way in which the distances between the planets go on increasing, has already been adverted to. The distances of the orbits of the successive planets from that of Mercury form a progression, each being nearly double of the preceding, as may be seen by inspecting the table of distances from the sun. Thus, Venus is distant from Mercury 32,000,000 miles; the Earth, 58,000,000; Mars, 108,000,000, &c. Before the discovery of the planetoids, there was a striking break in this progression between Mars and Jupiter, which first suggested the idea of a missing planet. Beyond Jupiter it is continued pretty closely, except in the case of Neptune, whose actual distance is much less than the progression requires. Astronomers now regard this remarkable numerical harmony as rather a casual coincidence than a real law.

A more important uniformity among the planets is, that their orbits lie all nearly in one plane. If we take the plane of the earth's orbit, which is the same as that of the ecliptic, as a standard of reference, and suppose it represented by a ring held horizontally with the sun in its centre, then the other orbits will be represented by other rings, two within, and the others without, held so as also to have the sun in the centre, and (with the exception of a few of the planetoids) never rising above or sinking below the level of the earth's ring more than a very few degrees. In consequence of this arrangement, the motions of the planets, as seen from the earth, are confined to a narrow zone of the heavens, extending about 8° on each side of the ecliptic (RT in the fig.). This circular belt, called the *Zodiac*, was from the earliest times divided into twelve equal parts, called



signs, containing, of course, 30° each. These signs received each a particular name, from the groups of stars or constellations in them having a fancied resemblance to certain figures, chiefly of animals. The names of the signs, with the symbols by which they are usually represented, are as follows :—

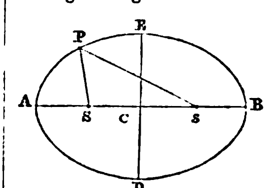
♈ Aries, the Ram.	♎ Libra, the Balance.
♉ Taurus, the Bull.	♏ Scorpio, the Scorpion.
♊ Gemini, the Twins.	♐ Sagittarius, the Archer.
♋ Cancer, the Crab.	♑ Capricornus, the Goat.
♌ Leo, the Lion.	♒ Aquarius, the Water-bearer.
♍ Virgo, the Virgin.	♓ Pisces, the Fishes.

This division of the zodiac affords a ready means of pointing out the place of a planet (*c*), or of the sun (S) or moon, at any particular time, by telling in what sign it is.

Besides moving nearly in one plane, the planets move all in one direction—namely, from west to east. The same law prevails among the satellites, with the remarkable exception of those of Uranus, which have a *retrograde* movement, or from east to west.

But the grand uniformities of the solar system are those discovered by the celebrated astronomer Kepler, and known as 'Kepler's Laws.' Kepler merely deduced them as matters of fact from the observations of himself and others; it remained for Newton to discover their cause. One of these laws respects the exact form of the paths in which the planets move. The ancients, from some imaginary perfection which they attributed to the circle, had taken it for granted that all celestial movements must be circular; Kepler made the important discovery that this is an error, and that the planetary orbits are *ellipses*.

The ellipse is an important figure in astronomy; for not only are the planetary orbits ellipses, but the planets themselves have an elliptical shape, as we saw when speaking of the form of the earth. There is a ready practical way of describing an ellipse, which at the same time gives a good sensible notion of its nature. If the ends of a thread are fastened by pins to two points S and *s*, at a distance apart less than the length of the thread, and if the point of a pencil P, is put into the loop of the thread, and moved round so as to keep it stretched, the pencil will trace an ellipse.



The two points S and *s* are called the *foci* of the ellipse; AB is the major or transverse axis, C the centre; and SC, the distance of the focus from the centre, is the *eccentricity*. With the same length of thread, a variety of ellipses may be described, by altering the distance between the points S and *s*. The nearer they are brought to each other, the rounder does the figure become; and when they come together, it forms a perfect circle. In the planetary orbits, the sun is always in the focus S, and therefore the planet is at different distances from the sun in different parts of its orbit. When it is at A, the nearest point, it is said to be in *perihelion;* and when at B, in *aphelion*. SE is the mean distance, and is equal to AC. The planetary orbits differ very little from circles, or have very little eccentricity. The earth's orbit, if accurately represented on paper, could not be distinguished from a circle by the eye; the difference between the greatest and least distances from the sun is about the thirtieth part of the mean distance.

Another of Kepler's laws connects the change of a planet's distance from the sun, with the speed of its motion: when the distance *increases*, the speed *diminishes;* and at the least distance we find the greatest speed. The calculation, however, must be made by squaring the distance. Thus, if the distance increased from 9 to 10, the velocity would diminish at the rate of 100 to 81. If, therefore, we know the change of velocity, we shall be saved from *observing*—for we can *calculate*—the change of distance. This law is called the law of *equal areas*, because the areas swept over by the line joining the sun and planet are equal in equal times. This line is termed the *Radius Vector*.

The two laws already noticed refer to the motions of a single planet; the third law shews a relation between the motions of all the planets, or all the bodies that revolve round the same centre. It is, that *the squares of the periodic times of any two planets are to each other as the cubes of their mean distances from the sun;* that is, if there be two planets, and one further off than the other, the near planet will perform its revolution quicker than the other, and according to a fixed proportion. Thus, the periodic times of the earth and Mars are 365¼ and 687 days, and their distances as 100 to 152⅓; and by Kepler's law the square of 365¼ is to the square of 687 as the cube of 100 to the cube of 152⅓; which, on making the calculation, will be found to be the case. This law goes still further to shorten the labour of observation, and increase the knowledge derivable from what is observed. If a new planet is discovered, the astronomer has only to observe its distance; this once known, the time of revolution can be determined, without waiting till we see it go actually round the heavens. This third law gives a sort of family relationship to all the bodies of the solar system, and shews that though they move widely apart from each other, yet their connection with a common centre maintains harmonious relations throughout the whole. The same three laws apply to the revolutions of satellites about their primaries.

DIURNAL AND ANNUAL MOTIONS OF THE EARTH.

The earth, like all the other planets, has two motions: it whirls round its axis once a day; and while doing so, it is all the while travelling bodily through space in a wide circuit round the sun, which it accomplishes in a year. The first is called a motion of *rotation*, the second of *translation*. The two combined give rise to the vicissitudes of day and night and of the seasons.

The circumference of the earth being 25,000 miles, any spot at the equator, in order to go round in twenty-four hours, must move upwards of 1000 miles an hour. This velocity decreases towards the poles, because the circles to be described become less; but in Great Britain it is still nearly 600 miles an hour. It is difficult, at first sight, to reconcile this notion with the impression we have of the 'firm earth,' which is to us the very emblem of fixedness and rest. But in order to learn to distrust our feelings in the matter, we have only to reflect how easily they are imposed upon in many familiar instances of a similar kind. While looking at surrounding objects from the deck of a smooth-going vessel or the window of a railway-carriage, the objects seem to be fleeting past, and we ourselves to be at rest. It is in this way that the swift, but smooth and noiseless whirl which carries the earth's surface and its inhabitants eastward, makes the starry vault seem to flit past the eyes of these inhabitants towards the west.

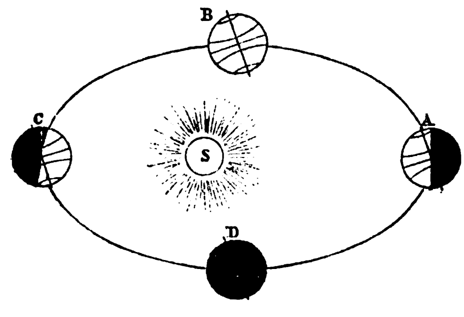
It is the earth's rotation that causes the vicissitude of day and night. The earth being a globe, only one-half of it can be in the sun's light at once; to that half it is day, while the other half is in its own shadow, or in night. But by the earth's rotation, the several portions of the surface have each their turn of light and of darkness. This happens because the position of the earth is such that the equator is on the whole presented towards the sun; had either pole been towards the sun, that hemisphere would have revolved in continual light, the other in continual darkness.

Length of a Day.—One complete rotation of the earth does not make a day, in the usual sense. If the time is noted when a particular fixed star is exactly south or on the meridian, when the same star comes again to the meridian the next day, the earth has made exactly

one rotation, and the time that has elapsed is called a *sidereal day*. This portion of time is always of the same length; for the motion of the earth on its axis is strictly uniform, and is, in fact, the only strictly uniform motion that nature presents us with. Sidereal time, or star-time, from its unvarying uniformity, is much used by astronomers. But the passage of a star across the meridian is not a conspicuous enough event for regulating the movements of men in general. It is not a complete rotation of the earth, but a complete alternation of light and darkness that constitutes their day. This, which is called the *civil* or the *solar* day, is measured between two meridian passages of the sun, and is about four minutes longer than the sidereal day. The cause of the greater length is this: When the earth has made one complete turn, so as to bring the meridian of the place to the same position among the fixed stars as when it was noon the day before, the sun has in the meantime moved eastward nearly one degree among the stars, and it takes the earth about four minutes more to move round so as to overtake him. If this eastward motion of the sun were uniform, the length of the solar day would be as simple and as easily determined as that of the sidereal. But the ecliptic or sun's path crosses the earth's equator, and is therefore more oblique to the direction of the earth's rotation at one time than another; and besides, as the earth moves in her orbit with varying speed, the rate of the sun's apparent motion in the ecliptic, which is caused by that of the earth, must also vary. The consequence is, that the length of the solar day is constantly fluctuating; and to get a fixed measure of solar time, astronomers have to imagine a sun moving uniformly in the celestial equator, and completing its circuit in the same time as the real sun. The time marked by this imaginary sun is called *mean solar time;* when the imaginary sun is on the meridian, it is *mean noon;* when the real sun is on the meridian, it is *apparent* noon. It is obvious that a sun-dial must shew apparent time, while clocks and watches keep mean time. Only in four days of the year do these two kinds of time coincide. In the intervals, the sun is always either too fast or too slow; and the difference is called *the equation of time*, because, when added to or subtracted from apparent time, it makes it equal to mean time. The mean solar day is divided into twenty-four hours, the hours into minutes and seconds. A sidereal day, we have seen, is shorter; its exact length is 23 hours, 56 minutes, 4 seconds of mean solar or common time. Astronomers divide the sidereal day also into twenty-four hours, which are of course shorter than common hours. In the course of a civil year of 365 days, the earth turns on its axis 366 times, or there are 366 sidereal days.

The earth, then, gliding noiselessly and steadily round on its axis, is the great time-keeper, and the heavenly bodies are the pointers or indices by which we note its progress. The art of reading off the hour of the day from the heavenly bodies is necessary in the important problem of *finding the longitude* at sea. (See MARITIME CONVEYANCE.)

The Seasons.—The way in which the earth's annual motion round the sun produces the alternations of the seasons, may be sensibly illustrated as follows:—Having placed a lamp or candle in the middle of a round table, to represent the sun, take a round ball with a straight rod passing through its centre, to represent the earth with its axis. Holding the globe over the north edge of the table (as at C, in the figure), on a level with the light, place the axis, not quite upright, but leaning northwards at an angle of 23° 28′ from the perpendicular; and the upper end of the rod being considered the north pole, we have the position of the earth with respect to the sun on the 21st of December, or winter solstice. By turning the ball on its axis, it will be seen that in the northern hemisphere any spot is longer in darkness than in light; while a considerable space round the pole never comes into the light at all, and has thus perpetual night as well as winter. In the southern hemisphere, again, every place is longer in light than in darkness, and a space round the pole has perpetual day.



In carrying the ball round the edge of the table to represent the earth's translation round the sun, care must be taken to keep the axis always *parallel to its original position*—that is, always with the same slope, and that slope pointing to the north. As we recede from C, the difference of illumination of the two hemispheres diminishes, till at B, one quarter round, the rays fall directly on the equator and reach to both poles, and as the earth turns, every spot on its surface, is as long in light as in darkness. This is the position at the *vernal* equinox on the 21st of March, when the days and nights are equal all over the earth. On the 21st of June, the summer solstice, the position is that represented at A, and corresponds to that at C, except that it is now the northern hemisphere that enjoys most of the sun's rays, or has summer, while the southern hemisphere is in winter. In moving through the remaining half of the circuit, the ball comes into a position at D similar to that at B, and representing the *autumnal equinox* on the 21st of September.

The earth is in perihelion on the 1st of January; it is then about 3,000,000 miles nearer to the sun than on the 1st of July; the sun's disk is slightly broader, and we might expect this circumstance to mitigate the severity of our winter, and to add to the heat of summer in southern latitudes. But owing to the action of the law already given, by which the velocity of a planet increases with its nearness to the sun, the earth passes over the perihelion half of its orbit in less time than over the other half, and thus the effects of greater proximity are counteracted.

It is this real motion of the earth in its orbit that causes the apparent motion of the sun in the ecliptic already described. If we conceive a wide circle, described outside the orbit, to represent the sphere of the fixed stars, when the earth is at A, the sun will appear to be at a point in this circle beyond C; and as the earth moves towards D, the sun will seem to travel along the outer circle in the direction of B. When the earth is at B, and the sun's rays fall perpendicular upon its equator, the sun will appear to be in the celestial equator, or in that point of the ecliptic where it crosses the equator, which is called the *equinoctial* point Aries. The earth's orbit, then, and the circle of the ecliptic, are in the same plane. If we conceive the orbit to be a solid ring or hoop, a sheet of parchment stretched over it like a drum-head would represent the plane of the orbit; and this sheet, extended straight in all directions to the concave of the fixed stars, would meet that concave in the circle of the ecliptic. It is to this plane that the orbits of all the other planets are referred; they cross it at small angles, and the points of crossing are called *nodes*.

A year, in the usual sense of the term, is the time

that the sun takes to move from either equinox back to the same equinox, or from either tropic back to the same tropic. This embraces a complete circle of the seasons, and brings the earth into the same position with respect to the sun; hence it is called a solar, equinoctial, or *tropical* year. If the equinoctial points remained fixed, this period would coincide with a complete revolution of the sun in the ecliptic, or—which is the same thing—of the earth in its orbit. But, owing to a cause which it belongs to physical astronomy to explain, the equinoctial points have a slow backward motion on the ecliptic of 50″ annually; when the sun, therefore, leaving the equinoctial point Aries one spring, arrives at that point next spring, he has yet 50″ to travel before he has completed a circuit among the stars, which makes a *sidereal year*. The return of the sun to the same equinoctial point thus *precedes* its return to the same point in the ecliptic; and this fact is known as the *precession of the equinoxes*. The length of the equinoctial or tropical year is 365 days, 5 hours, 48 minutes, 50·4 seconds; of the sidereal year, 365 days, 6 hours, 9 minutes, 10·4 seconds.

The equinoxes thus retrograde 1° in 71·6 years; and in 25,868 years they will make a complete revolution of the ecliptic. Celestial longitudes being counted from the point Aries, are slowly increasing: since the first catalogues were formed, the longitudes of the fixed stars are all greater by 30°.

The Calendar.—How the civil year, which must contain an exact number of *whole* days, is adjusted to the natural year, which contains fractions of a day, is explained in CHRONOLOGY.

Aberration of Light.—One direct proof of the earth's motion in its orbit is found in a phenomenon discovered by the illustrious astronomer Bradley. Vision, it is well known, arises from rays of light proceeding from any object, and entering the eye; and we see the object in the direction in which the rays have come. If both the body giving forth light, and that one which receives it, be at rest, the former will be seen in its true place, at least in so far as aberration is concerned; but let either of the bodies move, and this will not be the case. In order to render this plain: suppose a shower of hail to fall perpendicularly upon a number of tubes—say the pipes of an organ; if the organ remain stationary, the hailstones will descend sheer from the top to the bottom, without any deviation right or left; but move the organ in any direction, and they will strike the side opposite to the direction in which the motion is made. To make them descend to the bottom of the tubes in motion without striking, the tubes must be slightly inclined forward in the direction of the motion. This represents exactly the circumstances under which light from a heavenly body enters the eye or the tube of a telescope. The earth, bearing the spectator with his telescope, is moving at the rate of nineteen miles a second; light moves with the amazing velocity of 192,000 miles per second, vastly faster than hailstones, still requiring sensible time; and in order to adjust the telescope to these two motions, it must be directed, not exactly to the point from which the light proceeds, but slightly in advance of it. The object thus appears displaced, and the amount of displacement is *aberration*.

THE MOON.

Next to the sun, the moon is to us the most striking of all the heavenly bodies. Its disk is almost equal to that of the sun, the mean apparent diameter being 31′ 7″. The real diameter is 2153 miles, which makes its volume about the forty-ninth part of that of the earth. Its mass or weight, however, is only about the ninetieth part of the earth's mass; so that its density is not much above half that of the earth, or not quite three times the density of water.

The moon's orbit being elliptical, and the earth in one of the foci, its distance varies to the extent of 30,000 miles; and this causes a corresponding variation in its apparent diameter. The moon's disk is thus sometimes larger than that of the sun, so as to cause a total eclipse of the latter, when it passes over it. The moon's path in the heavens does not coincide with the sun's path or ecliptic, but crosses it at two opposite points, at an angle of 5° 9′. These two points are called the *moon's nodes*—that by which the moon passes from the south to the north side of the ecliptic being the *ascending* node, the other the *descending* node. These points change their position, so as to make a complete revolution of the ecliptic, in a retrograde direction, in 18·6 years. When the moon is nearest to the earth, it is in *perigee;* and when at its greatest distance, it is in *apogee*. These two points are called the moon's *apsides;* they shift their position on the ecliptic as well as the nodes, but in the opposite direction, or from west to east. This motion is called the *progression of the moon's apsides;* the revolution is completed in 8·85 years.

A month.—The moon goes round the earth in her orbit in about twenty-seven days; and this motion makes her seem to us to move eastward among the stars at the rate of a little more than the length of her own apparent diameter in an hour. The time that the moon takes to make one complete revolution round the earth—that is, to return to the same place among the stars—is called a *sidereal* month or lunation. But while the moon is performing this journey, the sun has also advanced, though at a slower pace, in the same direction; and it takes the moon upwards of two days more to overtake the sun, as it were, and get again into the same situation with respect to that luminary and the earth. When it has done so, it has completed a *synodic* revolution. The synodic period or lunation, then, is the period between two new moons, or two conjunctions of the sun and moon; it is the lunar month, and its mean length is 29 days, 12 hours, 44 minutes. The sidereal month is 27 days, 7 hours, 43 minutes.

The moon, besides revolving round the earth, also turns on its own axis, and, by a remarkable coincidence, the rotation on the axis is completed in exactly the same time as the revolution in the orbit; which is probably the case with all other secondary planets. In consequence of this coincidence, the same side of the moon is always turned towards the earth, as is evident from her surface presenting constantly the same easily recognised marks in the same positions.

Owing to the rotation of the moon on her axis being quite uniform, while her motion in her orbit is not so, a little more of her eastern or of her western edge is seen at one time than at another; and from the axis not being quite perpendicular to the plane of the orbit, the north and south poles of the moon lean alternately a little towards the earth, and give us an occasional peep further of the northern and southern regions. These phenomena are known by the name of the *moon's librations*—the one set being *librations in longitude*, the other, *in latitude*.

As the moon, turning on its axis once in a little more than twenty-seven days, presents every part of its surface in succession to the sun in that time, the *day* of the moon is consequently nearly a fortnight long, and its *night* of the same duration.

Phases of the Moon.—The light of the sun, falling upon the moon, is partly absorbed into its body; but a small portion is reflected or thrown back, and becomes what we call *moonlight*. The illuminated part, from which we derive moonlight, is at all times increasing or diminishing to our eyes, as the moon proceeds in her revolution round our globe. When the satellite is on the opposite side of the earth from the sun, or in *opposition*, we, being nearly between the two, see the whole of the illuminated surface, which we accordingly term *full-moon*. As the moon advances in her course, the luminous side is gradually averted from us, and the moon is

said to wane. At length, when the satellite has got between the earth and the sun, or into *conjunction*, the

Phases of the Moon.

luminous side is entirely lost sight of; the moon is then said to *change*. Proceeding in her revolution, she soon turns a bright edge towards us, which we call the *new-moon*. This gradually increases in breadth, till she is one quarter of her circuit from the sun, or in *quadrature*, when half the disk is illuminated, and it is then said to be *half-moon*. The luminary, when on the increase from *new* to *half*, is termed *crescent* (increasing); when between half and full, it is *gibbous* (hump-backed).

In the early days of the new-moon, we usually see the dark part of the body faintly illuminated, an appearance termed the *old-moon in the new-moon's arms*. This faint illumination is produced by the reflection of the sun's light from the earth, or what the inhabitants of the moon, if there were any, might call *earth-light*. The earth, which occupies one invariable place in the sky of the moon, with a surface thirteen times larger than the apparent size of the moon in our eyes, is then *at the full*, shining with great lustre on the sunless side of its satellite, and receiving back a small portion of its own reflected light—the 'reflection of a reflection.'

The moon's rays were till recently believed to be without heat; but by concentrating them in a lens of three feet diameter, the Italian philosopher Melloni obtained a sensible elevation of temperature.

The *physical condition of the moon* is in many respects remarkable. It is ascertained to be without any atmosphere, nor is there the least trace of liquid of any kind. The direct rays of the sun will thus shine for fourteen days with a fierceness far beyond anything experienced on the earth; but there can be no accumulation of heat, and on the unilluminated side the cold must be for other fourteen days more rigorous than on the summits of our loftiest mountains.

The aspect of the surface, seen through a powerful telescope, is singularly rugged and desolate. The whole

N.

Telescopic appearance of the Moon.

visible hemisphere is thickly covered with mountain masses, and these mountains form the brightest parts of the surface. The parts that have a more uniform gray tint were formerly supposed to be water, and received such names as the Sea of Cold, the Sea of Showers, the Sea of Nectar. They are now seen to be regions of land diversified with permanent inequalities, only of less magnitude than the more mountainous parts.

'The mountains of the moon are not mountains, in the common acceptation of the term; they are circular pits, hollowed out into the lunar substance, and surrounded by a ring-shaped elevated border, more or less abrupt and broken. The floor of the pit is in every case depressed far below the general surface of the moon; the ring-shaped ridges are therefore much more precipitous on the inner than on the outer side. Very frequently, one or more isolated peaks arise from the centres of these depressed floors. The lunar surface is completely studded with circular and rimmed depressions of this nature. Those of small size are too numerous to be counted. There are some that are not more than 300 or 400 yards across; others exceed 100 miles.'

These circular mountains are denominated, according to their magnitudes, *Bulwark Plains*, *Ring-mountains*, *Craters*, and *Holes*. The most remarkable of the ring-mountains is that called Tycho, after the illustrious Danish astronomer. It is situated towards the southern border of the disk, a little to the left, and may be recognised on the figure by radiant streaks proceeding from it like rays. The enclosure is a circle forty-seven miles in diameter, and the inner side of the ridge is as steep as a wall, and 16,000 feet high, while the height above the surrounding surface outside is only 12,000 feet. On the floor of the enclosed hollow stand a few isolated hills, one of them nearly a mile in height.

The heights of the solar mountains are measured by means of the shadows they cast during the phases. More than a thousand have been thus determined, several of which reach a height of 23,000 feet. Considering that the moon's diameter is little more than one-fourth that of the earth, the solar mountains are thus on a much grander scale than the terrestrial. The mountains of the moon have in many respects a volcanic character; but no trace of an *active* volcano has yet been discovered; and the vast dimensions of most of them, together with other circumstances, make it difficult, with respect to many of them at least, to conceive them as formed by volcanic agency.

The Moon and the Weather.—It is an almost universal belief that the changes of the moon influence the weather; but when put to the test of accurate observation, this opinion is found to be completely groundless: there is, in fact, no correspondence whatever between the changes of the moon and those of the weather.

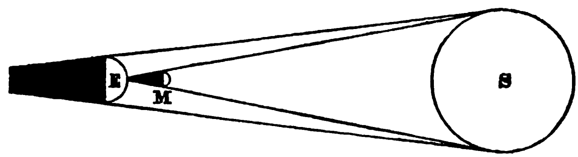
Innumerable other influences have been attributed to our satellite, extending over all nature; the growth of plants, the health or disease of animals and men, and the soundness of the mind, have all been supposed subject to her sway. Many of those fancies are dying out of themselves; they have as little foundation in fact as the peculiar 'moist' character which, in the days of astrology, was ascribed to the moon. The term *lunacy* is a relic of times when the human body was looked upon as a microcosm, in which the heart represented the sun, the brain, the moon, and every planet ruled its special organ. Yet the connection between the phases of the moon and paroxysms of insanity and other nervous disorders, seems supported by such an amount of testimony, that it still finds advocates, and even men of science like Arago recommend caution in deciding against it.

ECLIPSES.

Eclipses are caused by the positions of the earth and moon with respect to each other and to the sun. An eclipse of the sun takes place when the moon is between the sun and earth; and an eclipse of the moon is the result of the earth being between the sun and moon. In

other terms, the shadow of the earth cast upon the moon causes a lunar eclipse, and that of the moon upon the earth causes a solar eclipse.

The accompanying figure represents two positions of the moon: in the one she is in the earth's shadow, and totally eclipsed; in the other, her shadow is falling upon



a part of the earth's surface, and eclipsing the sun to that part. Within the limited circle on which the moon's shadow, or *umbra*, falls, no part of the sun is seen, or he is in *total* eclipse; within a larger space round that spot, the moon seems to cover only part of the sun's disk, making a *partial* eclipse; and this space is within the *penumora*, as it is called. When the moon happens to be so far distant from the earth that the cone of the shadow falls short of the earth, then a spectator standing immediately under the apex, or point, sees the moon covering the middle part of the sun's disk, and leaving a ring of it visible. This is an *annular* eclipse.

If the moon's orbit were in the same plane with that of the earth, there would be an eclipse of the sun at every conjunction, and one of the moon at every opposition; but as the two circles cross one another, it is only when the moon is in or near one of her nodes at the time of conjunction with the sun, that she can come nearly into a straight line with the earth and sun, so as to cover any part of the latter's disk, or that she can come into the earth's shadow at opposition. If a conjunction or new-moon happen while the moon is within about 16° of a node, the moon's disk will overlap, more or less, that of the sun. Now, the motions of the two orbs bring them within those limits at least twice every year, so that there *must* be annually *two* solar eclipses, and there *may* be *four*. The limits for a lunar eclipse are shorter, and a whole year *may* elapse without one occurring. There are thus more solar eclipses than lunar, though the general impression is to the contrary. This arises from the circumstance that, whenever an eclipse of the moon occurs, it is seen at all places where the moon is above the horizon, and the atmosphere unclouded; whereas an eclipse of the sun is confined to a limited tract.

These eclipses, like all other things about the heavens, can be predicted with almost perfect accuracy. It is also possible to calculate backwards, so as to find the probable date of remarkable eclipses recorded to have happened in antiquity.

Another effect that sometimes happens is the *occultation* of one body by another; as when the moon passes over a star or planet, and hides it from our view. This is quite different from an eclipse, which requires something to lie between a planet or satellite and the *sun*. The great breadth of the moon enables it to pass over a considerable number of stars every month.

The inferior planets, Mercury and Venus, sometimes cross the sun's face, on which occasion they may be traced by a telescope as a dark speck moving from one edge over to another, and then disappearing. These are *transits*, and are of importance in ascertaining the sun's parallax and distance.

In times when people's fates and fortunes were predicted from the positions of the planets at the hour of their birth, much stress was put upon *conjunctions* and *oppositions*. When two bodies are in the same quarter of the heavens, so as to be near one another, or have the same *longitude*, they are said to be in *conjunction;* when they are half a circle apart in longitude, they are in *opposition*. Astronomers use the sign ☌ to indicate conjunction; and ☍ to indicate opposition.

COMETS.

'Comets,' says Humboldt, 'at the same time possess the smallest mass, and occupy the largest space of any bodies in the solar regions; in their number, also, they exceed all other planetary bodies, except, perhaps, aërolites, amounting to many thousands at least.' Comets have usually two parts—a body or head, and a tail. The head has the appearance of a round nebulous mass of light, with usually a brighter part in the centre called the nucleus, but so far from containing anything solid, that the smallest stars are seen through the densest part of the substance. The tail is a still lighter luminous vapour, surrounding the body, and streaming far from it in a direction generally opposite to that in which the sun is situated, as if repelled by that luminary, and often curved. A vacant space has been observed between the body and the enveloping matter of the tail, which also appears sometimes less bright along the middle, immediately behind the head, as if it were a stream which the head had parted in two.

Whether comets are self-luminous, or derive their light from the sun, is a doubtful point. The tail is by no means essential to a comet; by far the greater number have no such appendage, appearing merely as a nebulous disk. In some cases, the tail has been seen gradually to form as the comet approached the sun, and to go through a number of striking transformations. Several distinct tails have at times been observed.

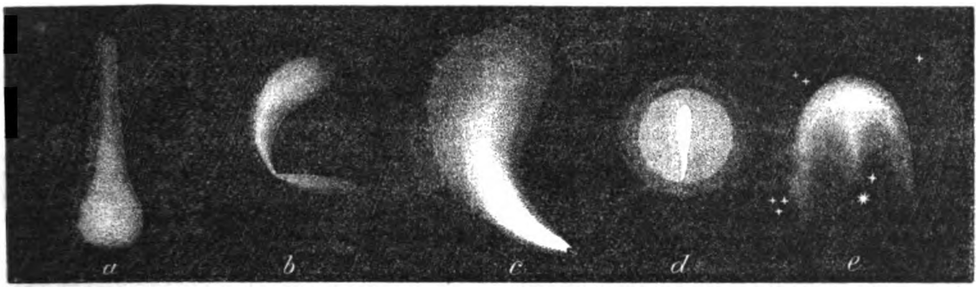
With regard to the motions of the comets, instead of revolving, like the planets, nearly in the plane of the sun's equator, it is found that they approach his body from all parts of surrounding space. At first, they are seen slowly advancing, with a comparatively faint appearance. As they approach the sun, the motion becomes quicker, and at length they pass round him with very great rapidity, and at a comparatively small distance from his body. The comet of 1843 approached within one-seventh of his radius. When near the sun, their brilliancy is greatly increased, but their volume is contracted. As they recede, their motion becomes gradually slower, and their brilliancy diminishes, and at length they are lost in distance.

In moving round the sun, comets obey the same general laws that regulate the planets. They do not, however, all describe ellipses; for Newton has shewn that a body moving round another by the force of gravitation, may move in any of the curves called *conic sections;* that is, in an ellipse, a parabola, or a hyperbola. Of the 200 cometary orbits that have been ascertained, about forty are known with greater or less certainty to be ellipses; while the others passed through our system in hyperbolas or parabolas—mostly the latter—open curves, which never return into themselves, but go on widening to infinity. Now, the comets that move in shut orbits, or ellipses, must return to the sun again and again, and may therefore be considered as members of the solar system. The others are only casual visitors; they can never return, but must run off into the immensity of space.

The most remarkable of the comets ascertained to return is one usually denominated Halley's Comet, from the astronomer who first calculated its period. It revolves round the sun in about seventy-five years, its

last appearance being at the close of 1835. The annexed cut represents some of the various appearances it presented on that occasion in different parts of its orbit—*a*, *b*, *c*, in approaching the sun; *d*, *e*, in retreating.

Another, called Encke's Comet, from Professor Encke



of Berlin, has been found to revolve once in 1207 days, or 3⅓ years; but in this case the revolving body is found, at each successive approach to the sun, to be a little earlier than on the previous occasion; as if, from some retarding cause, its orbit were gradually lessening, and as if the comet might consequently in time fall into the sun. The cause of this obstruction is supposed by some to be the ether whose vibrations are held to constitute light. A third, named Biela's Comet, revolves round the sun in 6½ years. It is very small, and has no tail. In 1832, this comet passed through the earth's path about a month before the arrival of our planet at the same point. If the earth had been a month earlier at that point, or the comet a month later in crossing it, the two bodies would have been brought together; what the consequences might have been, we know too little of the constitution of comets to judge. During its visit in 1846, this comet was seen to separate into two distinct comets, which kept moving side by side, till they disappeared. On the return of the comet in the autumn of 1852, the distance between the two nuclei had much increased, and their divorcement is now considered complete. Four comets, besides that of Halley, have periods a little over seventy years; to others have been assigned periods of many thousands of years, liable, however, to much uncertainty. Comets are often affected in their motions by the attraction of the planets; Jupiter, in particular, is said to be a perpetual stumbling-block in their way. In 1770, a comet got entangled amidst the satellites of that planet, and was thereby thrown out of its usual course, while the motions of the satellites were not in the least affected by its proximity. This proves the extreme lightness of the matter composing comets.

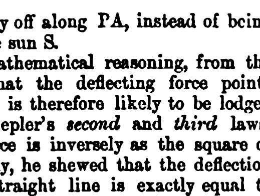
The comet now called Halley's, at its appearance in 1456, covered a sixth part of the visible extent of the heavens, and was likened to a Turkish scimitar. That of 1680, which was observed by Sir Isaac Newton, had a tail calculated to be 60,000,000 miles in length—a space two-thirds of the distance of the earth from the sun. There was a comet in 1744 which had six tails, spread out like a fan across a large space in the heavens.

MECHANICAL OR PHYSICAL ASTRONOMY.

Not long after Kepler had made those remarkable discoveries which completed the view of the regular courses and periods of the celestial motions; the *causes* of the motions, or the powers and forces whereby they are sustained, were also discovered by Sir Isaac Newton. He was the first to shew that the vast planetary balls whirl about their own centres, and fly through the celestial spaces, on exactly the same principles as a cannon-ball or a stone moves when thrown into the air. The principles of celestial mechanics, therefore, are the principles of motion discovered from the observation of bodies on the earth; they are the three Laws of Motion and the doctrines of the Composition of Forces, as illustrated under MATTER AND MOTION, and the doctrine of Universal Gravitation.

The fall of unsupported bodies to the earth is the most familiar action in nature; but it is not two centuries since Newton discovered that this action extends to the moon, the sun, and the planets. He proved that the moon is constantly falling towards the earth, and would fall into it, but for another motion she has, which is always carrying her off, and would of itself shoot her far away into space in a straight course; so that her actual circuit is the balance of two forces—one her weight, or gravity, towards the earth (*centripetal* force), the other an undying impulse to fly off at a tangent, like a whirled stone when the sling is let go (*centrifugal* force).

It was through the application partly of the laws of motion, and partly of Kepler's laws, that Newton established the universal prevalence of gravity. It being once found that the planetary motions could be kept up by a combination of forces; that is, by a force that projected the body once for all into free space with a great velocity, which, by the first law of motion, would be always kept up, whether it went off straight through space, or were compelled to go round a circle—and some second force to hold it in that circle; the great question arose, What is the *central* force—what power is it that causes the moon to fall towards the earth, instead of running off; and in like manner obliges the planets, with their immense speed, to keep constantly falling towards the sun? A planet P, if not held in by some tie, would fly off along PA, instead of being always carried round the sun S.



Newton proved by mathematical reasoning, from the *first* law of Kepler, that the deflecting force points exactly to the sun, and is therefore likely to be lodged in his body. From Kepler's *second* and *third* laws, he proved that the force is inversely as the square of the distance; and, finally, he shewed that the deflection of the moon from a straight line is exactly equal to the fall of a stone, if it were at the distance of the moon. The moon being sixty times further off from the earth's centre than we are, gravity is there 3600 times weaker; so that the speed acquired by a stone falling one second near the earth's surface, would be acquired only by falling an hour at the height of the moon. And it can be easily proved by calculation that the falling action of the moon is, in an hour, exactly that of a stone in a second. It being thus shewn that the moon is deflected by gravity, it was then concluded that the planets are deflected to the sun by the same cause; or

that gravity is the great *central* force throughout the solar system.

Newton also shewed that gravity is a *mutual* action; or that it is not the moon falling to the earth, but the earth and moon moving towards each other. If the two were equal, they would approach at an equal rate; but the earth being the largest, its approach to the moon is by so much slower than the moon's approach to it. The consequence is, that in the revolution of the moon, the centre is, not the earth's centre, but the centre of gravity of the earth and the moon, or that point between them where they would be equally balanced on a lever; so the sun, being attracted by all the planets, is not at rest, but is drawn about hither and thither; his enormous size preventing him from being moved very far. The centre of gravity of the solar system is not in the sun's centre, but between his centre and surface.

After thus identifying the mechanical causes of the planetary motions, Newton deduced all the laws of Kepler from the combination of the two great forces of Gravitation and Straight Impulse. In this way he found that these laws are not strictly true, as given by Kepler, and that therefore the prediction of the places from them could not be perfectly accurate. Not only was the sun's centre not the true focus of the ellipse, but he shewed that not one of the paths is an exact ellipse or a perfect oval. If there were only one planet to the sun, that planet would describe a perfect ellipse; for it can be proved that if a body is projected in free space, under the action of the sun's gravity, it must move round the sun, either in a circle, an ellipse, or in one of the other figures of the conic sections (the parabola and hyperbola); and Kepler's laws will be strictly true, taking the centre of gravity as the centre of the motion. But if a second planet is introduced, this planet is not only attracted by the sun (and the sun attracted by it), but there is an attraction between it and the first planet which disturbs the motion of both; neither of them can in this case move in an exact ellipse. The more planets there are, the greater the mutual action, and the more they are liable to be disturbed in their elliptic courses.

In like manner, if the moon and the earth were alone in the universe, the moon would go round the common centre of gravity of the two in a perfect ellipse; but as both move round the sun, and he acts upon both, very great deviations take place from the elliptic orbit; in fact, the application of Kepler's two first laws to the moon could never predict her place with anything like accuracy. The case is still worse with the satellites of Jupiter, which disturb one another, besides suffering disturbance from the attraction of the sun.

Perturbations.—But the same discoveries that shew the defects of Kepler's laws, give the means of correcting those defects, or of calculating the disturbing influences, so as to predict what the real motions will be under those disturbances. The whole series of these calculations make up the body of mechanical or physical astronomy; and the special disturbances are known as *perturbations* or *inequalities*. In calculating them, astronomers first suppose the case of one body revolving about a second, and disturbed in its regular orbit by a third; this is what is called the *problem of the three bodies;* the disturbing effect of each separate cause being thus found, the whole are then combined.

Masses of the Heavenly Bodies.—The theory of universal gravitation gives us the means of comparing the weights of the heavenly bodies, as if they were weighed on a steelyard. Thus the fall of the earth towards the sun in an hour, can be compared with the fall of the moon to the earth in an hour; and the two quantities multiplied by the squares of the two distances, will give the proportion between the mass of the sun and the mass of the earth, which is about 355,000 to 1. When we remember that the *bulk* of the sun exceeds that of the earth more than a million of times, we see that the matter of the sun is much lighter than the material of the earth. In the same way, Jupiter's mass is found to be 340 times that of the earth.

To find the actual density or specific gravity of the different bodies of the solar system, and compare it with a fixed standard, such as water, it is necessary to know the average density of the whole earth. This has been sought by comparing the attraction of some known body with the attraction of the globe. Thus, Dr Maskelyne attempted to calculate the attraction of a mountain in Perthshire, by finding how far it made a plumb-line to deviate from the perpendicular. In this experiment the plumb-ball was supposed to be attracted downwards by the general mass of the earth, and sideways by the mountain; and it could thus be seen how many times the whole earth surpassed the mountain in gravitating force. If the mountain itself then were measured, and its composition ascertained, so as to give the density of its rocky material, the entire mass of the mountain would be obtained, and from that the entire mass of the earth. The result of this experiment was, that the earth is, on an average, $5\frac{1}{2}$ times denser than water, or more than twice the density of granite or sandstone rock. Other experiments, of a different kind, have given much the same determination. From this we can estimate the densities of the sun, moon, planets, and satellites.

The Figures of the Heavenly Bodies, how caused.—It has already been seen that the sun and planets are, in general, round masses, with a slight flattening, which seems to be connected with the rapidity of their whirl. Now, both the general roundness and the flattening can be shewn to arise from ordinary mechanical laws, such as we see operating on the earth, provided we suppose that the planets were at one time soft fluid masses. If a fluid mass of attracting particles are left to themselves—that is, if there be no external compulsion, either attraction or pressure—they will always assume the *round* shape. Thus the drops of rain, and liquid drops in general, are nearly round; and they would be perfectly so if they were in free space, out of the reach of attracting bodies. On the same principle, a soft planetary mass, or a liquid satellite, would, by its own gravity, cohere into a round ball; so that the geometrical observation agrees exactly with the mechanical theory.

In the second place, the *flattening* is the consequence of the round balls being made to whirl, instead of remaining at rest. When a body is whirled, the matter at the surface acquires a tendency to fly off, so as to oppose the general attraction towards the centre. If the whirled body is soft or liquid, it cannot remain at rest, or in equilibrium, in its round form, inasmuch as the matter at the equator is rendered lighter by its centrifugal tendency, and is not a sufficient balance for the matter at the poles. To restore the balance, there must be a greater depth from the equator to the centre than from the poles to the centre; in other words, the equatorial width must exceed the polar width, which is what we actually find in all the revolving bodies. The planets also that revolve the most rapidly, as Jupiter and Saturn, are found to be the most elliptical.

That the matter on the equatorial regions of a planet gravitates less than at the poles, is proved by experiments on the earth. Bodies are found to weigh less in tropical countries than in high latitudes. The fall of a stone is less rapid, and the swing of a pendulum is slower; all shewing a diminished gravity.

Tides.—The tides are those regular movements of the sea whereby it rises and falls on its shores about twice a day. They may be regarded as a slight disturbance of the figure of the earth, caused by the attraction of the sun and moon. The methods of calculating them are similar to the investigations of the general question of the figure; hence they are regarded as a portion of the same subject. They are more particularly described under PHYSICAL GEOGRAPHY.

Precession of the Equinoxes.—It has been already

explained in what this consists—namely, in a slow retrograde motion of the equinoctial points upon the ecliptic, carrying them from east to west at the mean rate of 50″ in a year. The cause is to be found in the combined action of the sun and moon on the protuberant mass of matter accumulated at the earth's equator, which tends to alter the position of that equator with regard to the plane of the ecliptic. The exact nature of this action is too complex for description here; but combined with the rotation of the earth on its axis, the result is the regression of the equinoctial points above mentioned; while, as a necessary consequence, the celestial pole describes, at the same rate, a circle among the stars round the pole of the ecliptic at a distance equal to the obliquity of the ecliptic. Its motion, however, is not quite uniform or straight, but in a waving line, alternately approaching and receding from the pole of the ecliptic. This secondary disturbance, which is caused by the fluctuating position of the moon's nodes, is known as the *nutation* of the earth's axis.

The poles of the earth do not, then, point always to the same places among the stars. The present position of the north pole is within a degree and a half of a bright star in the constellation of the Lesser Bear. Its motion will bring it gradually nearer until it is within half a degree of that star, after which it will recede from it. Its course may be traced by drawing a circle on a celestial globe round the north pole of the ecliptic, at the distance of 23½°. The celestial pole describes this circle in 25,868 years. Twelve thousand years hence, it will be near one of the brightest stars in the heavens, called α Lyræ, which will then be the pole-star.

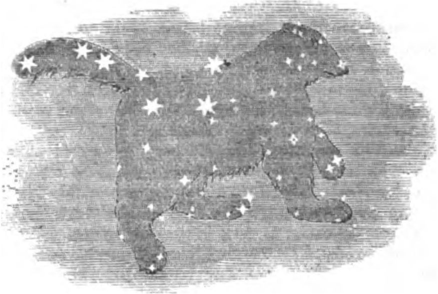
Stability of the System.—It is natural to inquire whether the numerous perturbations which all the bodies are subject to, are such as in the long-run to overthrow the present arrangements of the system. If any cause were at work to diminish steadily the mean distance of a planet, it must of course ultimately fall into the sun. It has, however, been proved that the total effect of all the mutual disturbances has no such tendency. Though there are secular variations that may go on increasing for thousands of years, they will necessarily decrease continually for periods of like duration, and the limits within which this secular oscillation is confined are in all cases extremely narrow.

The only thing that can bring about a decay in the system is a resisting medium—that is, if the planetary spaces, instead of being perfectly blank and void, are filled with a very thin gas or ether that would impede the motion of bodies, as our own atmosphere resists any body that is impelled through it. It is at present doubtful if such an ether exists; it is certain that, if it does exist, it is exceedingly rare, and cannot produce any perceptible effect in less than thousands of years; still, if it exist at all, it will tell some time or other, and will have the effect of lessening the mean distances, and contracting the orbits. The question of a medium is expected to be decided by the study of the comets.

SIDEREAL ASTRONOMY—THE FIXED STARS.

The first thing that strikes us about the stars is their difference as to brightness. They can be classified according to this feature. The most brilliant are said to be of the first *magnitude;* the next of the second; and so on. The smallest stars visible to the naked eye are of the sixth or seventh magnitude. The number of stars visible in one hemisphere may be about 2000, making in all 4000. About twenty-four are reckoned of the first magnitude. By using telescopes, a vast mass of new stars come into view, which are reckoned as far as the seventeenth magnitude; the numbers and closeness increasing with every increase of the telescope's power.

From the earliest times, the stars have been divided into groups called *constellations*, which were named from fancied resemblances to animals or other figures. Thus, a group in the northern part of the sky is called *Ursa Major*, or the Greater Bear. From the figure of the



Constellation Ursa Major.

seven more conspicuous stars, it is sometimes called *the Plough*. Another well-marked group is called after the mythical personage *Orion*. Individual stars are indicated by the letters of the Greek alphabet or by numbers, as η *Ursæ Majoris* (in the tip of the tail of the Greater Bear), 24 *Comæ*. Some remarkable stars have names, as Aldebaran (α *Tauri*), Sirius (in the nose of Canis Major). By means of a celestial globe, or a set of star-maps, the more conspicuous constellations may be soon recognised.

The stars are believed to be so many suns, shining by their own light, and each being perhaps the centre of a system of planets, the abodes of sensitive and intelligent existence. Their immense distance reduces them all equally to mere points of light; in the most powerful telescopes they shew no *disk*, and differ from one another, not in *magnitude*, properly speaking, but in brilliancy.

When the same methods of measurement that determine the distances of the sun and planets, were applied to the fixed stars, they seemed for a long time to fail. Two observations of any star made from different points of the earth's orbit, though at the enormous distance of 200,000,000 miles apart, gave no appreciable displacement or parallax. As a parallax of one second ($\frac{1}{3600}$) of a degree would imply a distance equal to 200,000 times that of the sun, and as it was certain that a parallax of that amount could be measured if it existed, it was inferred that no star was at least within that distance. More refined modes of observation have recently detected the parallax of several stars, and determined positively their distances. In stating these distances, it is convenient to take as a standard or unit the distance due to a parallax of one second—namely, 200,000 distances of the earth from the sun, or twenty millions of millions of miles, a space which it takes light 3¼ years to traverse, though it travels 192,000 miles per second. The nearest yet measured is a fine double star in the southern hemisphere (α Centauri), calculated to be a little greater than one such sidereal unit; Sirius, the brightest of the fixed stars, is at a distance of about four units, or eighty millions of millions of miles, requiring upwards of twelve years for the transmission of its light.

Temporary and Periodical Stars.—It is ascertained, beyond doubt, that some stars, at one time visible, and registered by ancient astronomers, are not now to be seen; while many instances are on record of stars which have come into sight for a time, and then gradually vanished. Besides these temporary stars, there are others that undergo periodical increase and diminution of lustre, and are called *periodical stars*. The star Omicron, in Cetus, for instance, goes through a series of variations in a period of about 330 days. It is seen as bright as a star of the second magnitude for about a fortnight; then gradually diminishes for three months, till it becomes invisible, in which state it remains for five months, when it again becomes visible, and gradually increases till it regains its former brightness, more or less—for it does not always reach the same

degree of lustre. There are eleven other stars which exhibit analogous phenomena, some of them at intervals of 500 years.

Binary and Multiple Stars.—Another variety in the nature of these luminaries is their being in some instances not *single* stars, as they appear to the naked eye, but a group of two or more, evidently, from their motions, forming one system. The star Castor, one of the Twins, is found, when much magnified, to consist of two stars, of between the third and fourth magnitude, within five seconds of each other. Upwards of 6000 such groups have been observed. Many of the double stars, no doubt, are thus accidentally brought together, the one being at a great distance behind the other; but of a great number, it has been fully ascertained that they are each a system, with a reciprocal relation to each other. They are therefore called *binary stars*, or more properly, *multiple* stars. It is generally observed that they move round each other within a certain time, and in elliptical orbits; the revolution of Castor, for instance, is supposed to be accomplished in 252 years.

Proper Motion of Stars.—When we speak of the stars being *fixed*, it is only as compared with the planets. There is no such thing as absolute fixity in the universe. Besides the revolutions of the double stars, a great many stars have been observed to be slowly but constantly carried away from their places in the heavens. This *proper motion*, as it is called, has in one instance shifted the situation of a star in the heavens, in the course of fifty years, over $\frac{1}{17}$th of a degree. Founding upon these displacements of the stars, it has been concluded that our sun, accompanied by his attendant planets, is in motion towards a region of space in the direction of the constellation Hercules. The velocity assigned to this movement is 422,000 miles a day. Some astronomers have even sought to assign a centre of gravity about which our whole star-system is in rotation.

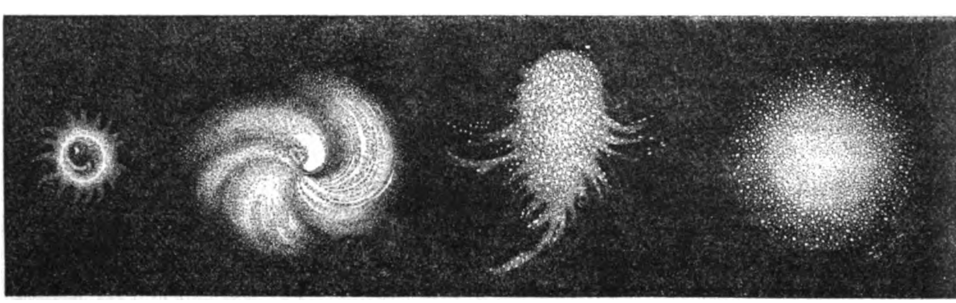
Milky-way.—The stars are very unequally scattered over the sky. We may always observe a whitish band arching the heavens, called the *Milky-way*, which appears to the eye, and still more to the telescope, as a dense mass of starry dust. Sir William Herschel, by gauging, as it were, the depth of the starry stratum in all directions, came to the conclusion, that the stars forming our firmament do not extend indefinitely into space, but are limited in all directions, the mass having a definite shape. He conceived the stratum to be thin in proportion to the length and breadth, and that looking through the mass of stars forming the depth in these directions, gives the appearance of the Milky-way. As the Milky-way divides into two branches, there must be a bifurcation of the stratum. Our place in the system is conceived to be not in the centre, but nearer to one end and to one surface.

Remote Star-systems, Nebulæ.—From the grand idea of the solar system, we thus rise to the vastly grander idea of a *stellar* system, composed of countless myriads of solar systems, many of them, perhaps, surpassing our own in magnitude, and held together by the universal bond of gravitation. But this star-system, which we may call our own, inconceivably vast as it is, is but an item of the heavenly inventory. Far beyond its bounds, the modern telescope has descried similar systems in great numbers, each hanging in some tolerably defined shape in the depths of space, and generally capable of being resolved, if not exactly into stars, into what has been expressively called *star-dust.*

A few of these remote systems are visible to the naked eye, as faint luminous spots in the heavens; but by means of powerful telescopes, more than 4000 have been observed and catalogued. They are generally spoken of collectively as *nebulæ*, from their cloud-like appearance. Many of them are resolvable into individual stars, even with a moderate telescope, but others were found to resist even the powerful telescope of Sir William Herschel; and he accordingly made a distinction between clusters of stars, or resolvable nebulæ, and nebulæ properly so called, which presented no appearance of stars. These last were conceived to be elementary sidereal matter in a diffused and gaseous form—matter in the course of being condensed to stars and systems—belated portions, so to speak, of the same soft and diffused material which, countless ages ago, was condensed into the defined bodies forming the remainder of our star-system! But in 1846, the powerful telescope of Lord Rosse shewed that one of the most marked of these nebulæ (that in Orion) did really consist of an immense irregular mass of stars, previously undiscernible, from being situated so remotely in the depth of the starry spaces. It has consequently been pronounced as extremely doubtful if there are any masses of diffused or, properly speaking, nebulous matter in the regions of space.

These star-systems are of various forms, but in general, as has been said, tolerably well-defined. Several exhibit to Lord Rosse's telescope most remarkable and even startling shapes. In the *Magellanic clouds*, a nebulous object in the southern hemisphere, there is one remote star-system, compared by Sir John Herschel to '*a bunch of ribbons disposed in what is called a true-lover's-knot!*'

The resolution of nebulæ into stars, however it may



Nebulæ and Clusters.

affect theories, infinitely exalts our conceptions of the magnitude and extent of the material universe. 'Look,' says Professor Nichol, 'at a cloudy speck in Orion, visible, without aid, to the well-trained eye; *that* is a stellar universe of majesty altogether transcendent, lying at the verge of what is known. Well, if any of these lights from afar, on which the six-feet mirror is now casting its longing eye, resemble in character that spot, the systems from which they come are situated so deep in space, that no ray from them could reach our earth until after travelling through the intervening abysses during centuries whose number stuns the imagination. There must be some regarding which that faint illumination informs us, not of their present existence, but only that assuredly they were, and sent forth into the Infinite the rays at present reaching us, at an epoch further back into the past than this momentary lifetime of man, by at least *thirty millions of years!*'

GEOLOGY.

GEOLOGY (from the Greek *gé*, the earth, and *logos*, discourse) is that science which treats of the materials composing the earth's crust, their mode of arrangement, and the causes which have produced that arrangement. By the earth's *crust* is meant that external shell or covering of solid matter which is accessible to man's investigation; the term being used in contradistinction to the interior mass, respecting the nature and composition of which we can know nothing by inspection. Though this crust is of no great thickness, it presents a great multitude and variety of matters for inspection, and reveals to us inductively an ancient history of the most interesting kind. We trace in it a long series of physical events, many remarkable changes of the surface, and a progressive march of animal and vegetable life throughout a long succession of ages prior to the existence of man. The science must therefore be regarded as one of high dignity and importance, even as a mere department of the knowledge possessed by our species. It has also, however, a still more interesting aspect, in the guidance which it gives us regarding many useful mineral substances.

The inorganic materials of the earth's crust are presented to us in three leading varieties of form and character—first, rocks of a crystalline texture, generally seen in irregular masses, and believed to have been formed by fire—second, rocks of argillaceous, arenaceous, calcareous, or other material, always seen in beds or strata, and manifestly produced as a sediment from water—third, metallic ores irregularly scattered throughout the above rocks. For the present, we shall lay aside the last, as falling properly under the science of Mineralogy, and devote our attention exclusively to the rocks and the organic remains contained in them.

CAUSES MODIFYING THE EARTH'S CRUST.

Taking appearances presented by rocks, in connection with operations which we see going on upon the earth's surface at the present day, we become aware that the inorganic materials of the earth's crust have been subjected, throughout the long succession of ages just spoken of, to determinate natural laws effecting in them a great variety of modifications. Two great agents, which have at all times impressed themselves strongly on the senses of mankind—Fire and Water—are seen to have wrought vast results; besides a third, of whose force we are less apt to be aware—the Atmosphere. Through these causes, new masses have been brought from below to the surface, others have been worn down so as to constitute new rocks, the *low* of one period has been made the *high* of another, and *vice versâ:* to these operations, mixed throughout with the results of animal and vegetable life, the whole phenomena of geology are attributable.

The causes in question have been classified by geologists as *Degrading* and *Elevating*. These they consider as antagonistic to each other; the one as a constant agent of destruction, the other as an equally constant repairing or reproducing power, and the effect being a kind of equilibrium between sea and land.

Degrading Causes.—The degradation, wearing down, or (so to speak) destruction of the sub-aërial parts of the earth's crust, is brought about by the chemical and mechanical forces of air and water. In the first place, the disintegration or separation of particles may be effected chemically by the absorption of oxygen and carbonic acid from the atmosphere into the rock-surface which is exposed to it. This is a process continually going on. We have its effects conspicuously displayed on the surface of a hill of trap-rock, where we see first a light brown powdery soil, then a splintery bed of several inches thickness, and below that the solid rock, the process of disintegration in that rock being first into splinters, and afterwards into powder. Even granite, which is regarded as an extremely hard rock, is sometimes found pulverised in this way to the depth of several feet.

Again, water percolates through minute fissures in rocks. When frost arrives, the water freezes and swells, and thereby dislodges parts of the rock, which are precipitated into lower levels. Or it may meet some clayey veins or strata, hitherto sufficient to keep various masses together: these veins or strata, being gradually softened by the water, lose their power of cementing the masses; and the upper then fall away or slide into a lower level. A *slide* of rock from the Rossberg, in Switzerland, in 1806, filled the bottom of the vale below, destroying many villages, and causing the loss of 800 lives. The impulse of wind and rain on the surface of rock is also of great efficacy in pulverising and wearing it down, sharp points being rounded, and soft parts hollowed. In Sweden there are some large detached masses of granite, containing perforations produced by this cause, some so very large as to admit of a horse and cart passing through them. These effects may be considered as chiefly *mechanical.*

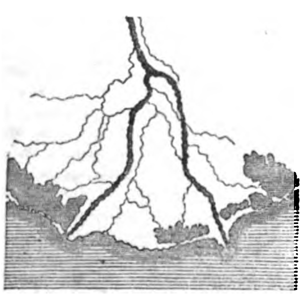
When water collects into channels, and follows its well-known tendency to find the lowest level to which it has access, it becomes a mechanical instrument of still greater force for wearing down the land. In its smallest rills, as it descends the mountain side, it cuts into the soil, and carries off whatever particles it can disengage. When gathered into brooks, its operations are still more powerful. When one of these is placed amongst mountains, every heavy shower swells it into an impetuous river, by which large quantities of detached rock and soil are brought down. In the upper parts of the courses of almost all rivers, the greater speed of descent makes up for the smaller volume of water, as far as the power of bringing down stones and soil is concerned. Again, in the lower part of the course, the smaller speed is sometimes compensated by the unevenness of the course; in which case the water is incessantly driven from one projection of the banks against another; and by that means wears away a great quantity of solid matter. The mere flowing of pure water would exert little influence on hard rocks; but all rivers carry down sand and gravel according to their velocity;* and these, by rubbing and striking against the sides and bottoms of the channel, assist in scooping out gullies and ravines, which everywhere present themselves. The Nerbudda, a river of India, has scooped out a channel in basaltic rock 100 feet deep. The river Moselle has worn a channel in solid rock to the depth of 600 feet. Sedgwick and Murchison give an account of gorges scooped out in beds of the rock called conglomerate, in the valleys of the Eastern Alps, 600 or

* It has been calculated that water running with a force of three inches per second will tear up fine clay, six inches will lift fine sand, eight inches sand as coarse as linseed, and twelve inches fine gravel; while it requires a velocity of twenty-four inches per second to roll along rounded pebbles an inch in diameter, and thirty-six inches per second to sweep forward angular stones of the size of a hen's egg.

700 feet deep. A stream of lava, which was vomited from Etna in 1603, happened to flow across the channel of the river Simeto. Since that time, the stream has cut a passage through the compact rock to the depth of between forty and fifty feet, and to the breadth of between fifty and several hundred feet. The cataract of Niagara, in North America, has receded, according to most authorities, nearly fifty yards during the last sixty years. Below the Falls, the river flows in a channel upwards of 150 feet deep, and 160 yards wide, for a distance of seven miles; and this channel has manifestly been produced by the action of the river.

Sometimes, during floods, rivers produce great changes in very short periods. A flood caused by the bursting of the barrier of a lake in the valley of Bagnes, Switzerland, moved at first with the tremendous velocity of thirty-three feet per second. From the barrier burst by the waters to Lake Geneva, there is a fall of 4187 Paris feet; the distance is forty-five miles; and the water flowed over all this space in five hours and a half. It carried along houses, bridges, and trees; and masses of rock equal in size to houses were transported a quarter of a mile down the valley.

The matter carried down by rivers is often deposited at their sides, when it constitutes what is called *alluvial land;* sometimes it is deposited at the bottom of lakes, when it forms what are termed *lacustrine deposits.* In many instances it has been deposited in large quantities at the mouths of rivers, giving rise to alluvial flats, which, from their resemblance in shape to the Greek letter Δ, have been denominated *deltas.* The triangular form of a delta, like that of the Nile (see fig.), for example, is produced by the river at a certain point inland dividing itself into two main streams, which gradually diverge till they reach the ocean, enclosing the space which constitutes the delta. As an instance of the vast extent of new land formed at the mouths of rivers, the delta of the Ganges is 220 miles in one direction by 200 in another.



Delta of the Nile.

The matter carried down by rivers, and thus deposited, is small in amount compared to that transported to the ocean. The quantity of sand and mud brought down by the Ganges to the Bay of Bengal, is in the flood-season so great that the sea is discoloured with it sixty miles from the river's mouth. Sir C. Lyell estimates the quantity of solid matter brought down by this river every day as equal in bulk to the greatest of the Egyptian pyramids. According to General Sabine, the muddy waters of the Amazon River may be distinguished 300 miles from its embouchure.

The constant action of the sea upon the land is strikingly apparent to the inhabitants of coasts. Whole islands have been destroyed by the action of tides, waves, and oceanic currents, while the remains of others rise above the surface of the water like the ruins of some desolated city. Many instances of the encroachment of the sea upon the land have been recorded. An inn on the coast of Norfolk, built in 1805, then seventy yards from the sea, was in 1829 separated from the coast by only a small garden. A church on the coast of Kent, which, in the reign of Henry VIII., was a mile inland, is now only about sixty yards from the water's edge. The island of Nordstrand, on the coast of Schleswig, was, in the thirteenth century, fifty miles long and thirty-five broad. About the end of the sixteenth century, it was reduced to an area of only twenty square miles. The inhabitants erected lofty dikes for the purpose of saving their territories; but in the year 1634, a storm devastated the whole island, by which 1340 human beings and 50,000 head of cattle perished. A little to the north of the present island stands Nordstrand-moor, which, before being separated by the sea, was a portion of the island of Nordstrand.

The matters thus worn off the elevated parts of the earth's surface, and deposited in the sea, sink and are spread out at the bottom in beds or *strata,* which subsequently become hardened into rocks, as is believed, by heat and pressure. It is a process continually going on, and which would in time carry all dry land into the ocean, and reduce our planet to a plain spherical mass, were there not a counteraction in certain forces tending as constantly, though more intermittingly to the elevation of the masses so formed in the bed of the ocean.

Elevating Causes.—As degrading forces are chiefly owing to water, so those of an elevating character are chiefly owing to fire; they are therefore sometimes comprehended under the term *Igneous Agency.*

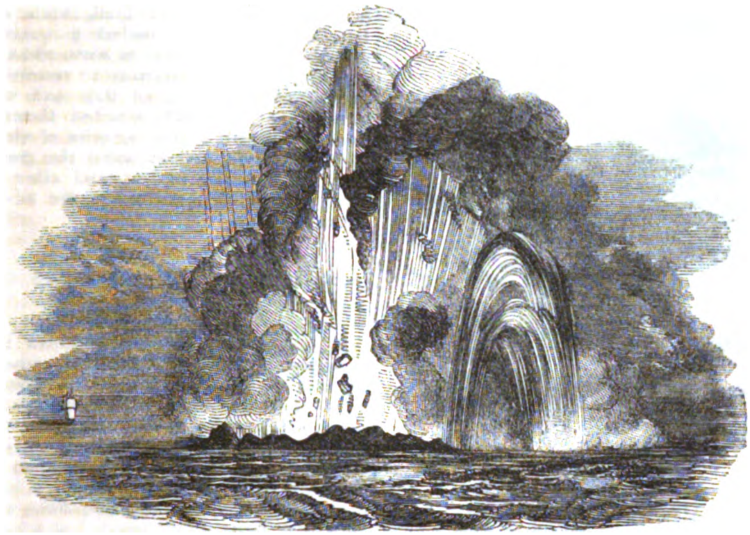
The manifestations of igneous agency at present observable may be considered under three heads—namely, *volcanoes, earthquakes,* and *gradually elevating forces.* These phenomena may be viewed as the effects of subterranean heat, operating under different circumstances. A volcano may be described as an opening in the earth's surface, bearing the general appearance of a vent of subterranean fire, and through which smoke, cinders, and ashes are almost continually issuing, but which sometimes discharges great fragments of rock, and vast quantities of melted rocky matter or *lava.* The general effect is a throwing up of earthy material, in a conical form, from a low to a high level, of which Mount Etna is one of the most characteristic examples.

Geographers at present reckon about 200 volcanic vents in activity throughout the earth. The greater number of the whole are in a line along the west coast of South and North America. There are many in the islands of the Pacific and Indian Oceans, and in the central regions of Asia. In Europe there are only three in activity—Etna in Sicily, Vesuvius in Italy, and Hecla in Iceland. But a vast number of hills throughout France, Britain, and other countries, bear the appearance of having once been active volcanoes. As volcanic action often takes place in the bed of the sea (submarine volcanoes), and as there are probably many on land not yet described by geographers, the number of such vents throughout the earth must be considerably more than two hundred.

Of the power of volcanoes to throw up large quantities of solid matter, we have many examples. During an eruption of Etna, a space around the mountain, 150 miles in circumference, was covered with a layer of sand and ashes, generally about twelve feet thick. In the first century, the cities of Herculaneum and Pompeii were buried beneath such a layer of matter by Vesuvius. In 1660, the philosopher Kircher, after accurately examining Etna, and the ground adjoining its base, calculated that the whole matter thrown out by it at its various active periods would form a mass twenty times as large as the mountain itself, which is 10,870 feet high, and thirty miles in diameter at the base. From this mountain, in 1775, there issued a stream of lava a mile and a half in breadth, twelve miles long, and 200 feet thick. At an earlier period, there was a stream which covered eighty-four square miles. In 1538, a large hill, since named Monte Nuovo, was thrown up in the neighbourhood of Naples in one night; and in 1759, in a district of Mexico previously covered by plantations, a sudden outburst of volcanic action, which

lasted several months, terminated in leaving six hills, varying from 300 to 1600 feet in height, above the old plain.

Of the effect of submarine volcanoes some interesting observations have been made in recent times. In June 1811, an island was thrown up by volcanic agency near St Michael in the Azores. Columns of cinders rose 700 or 800 feet above the surface of the sea, with a noise resembling that of distant artillery. In the course of a few days the island was a mile in circumference, and



Hotham Island, Mediterranean, in 1831.

about 300 feet in height, having a crater in the centre full of hot water. Some time afterwards it disappeared. In July 1831, a similar island was thrown up, under precisely similar circumstances, in latitude 37° 11′ north, and longitude 12° 44′ east, off the coast of Sicily. It consisted of stones, mud, and cinders, and was of circular form, about a mile and a half in circumference, with a crater of hot water in the centre 400 yards in diameter. This island, named Sciacca, or Graham's Island, existed so long above the sea as to allow of many persons landing upon it. The Bay of Santorin, in the Greek Archipelago, which is about six miles long and four broad, contained, a few years ago, three volcanic isles, the first of which rose about the year 200, the second in 1650, and the third in 1709. In a part of the bay where the water is generally several hundred feet deep, a shoal has for several years been gradually rising: about 1816, there were fifteen fathoms water upon it; in 1830, there were only three or four; and later accounts reduce it to two and a half fathoms. This rising mass was ascertained to be of solid rock, about half a mile in length by one-third of a mile in breadth; the water deepening suddenly all round it.

Many islands which have long been inhabited by man bear all the appearance of having risen in like manner from the bosom of the deep. The islands of St Helena and Ascension, the Azores, the West India Islands, Iceland, and many of the islands in the Pacific, are evidently the produce of volcanic action. 'Owyhee,' says De la Beche, 'is a magnificent example of such an island: the whole mass, estimated as exposing a surface of 4000 square miles, is composed of lava, or other volcanic matter, which rises in the peaks of Mouna Roa and Mouna Kaa to the height of between 15,000 and 16,000 feet above the level of the sea.'

The causes of earthquakes have not as yet been satisfactorily explained, but they are now generally allowed to be connected with volcanic agency. They occur less frequently, and generally with less tremendous effect in Europe than in some other parts of the world—those parts where volcanic agency is most active being also the parts where earthquakes are most frequent and most dreadful. Though their effect is sometimes to cause a sinking of the ground, they may, upon the whole, be considered as among elevating causes. It is conceived that they are produced by gases confined in the molten interior of the earth, similar to those which find vent by volcanoes. Such gases, prevented by local circumstances from escaping, may, it is thought, thus shake the solid ground over a large tract, and even cause it to rise to a certain extent above its former level. The most striking proof which has been adduced in support of this doctrine, is the effect of the earthquake which took place in Chile in 1822. This is the part of that continent in which volcanoes are most numerous and active. On the occasion referred to, a shock was felt along the coast for more than 1000 miles. The land for 100 miles along the coast, and backwards to the line of the Andes, was raised above its former level. At the shore, and for some distance along the bottom of the sea, the rise was three or four feet; so that rocks formerly submerged, and covered with shell-fish, were now exposed above the sea. Old beaches, similar to that now raised, have also been observed in parallel lines along the coasts of Chile and Peru, ranging, according to Mr Darwin and M. Von Tschudi, from 20 to 120 feet above the ocean.

It has since been observed that old beaches, similar to those in Chile, exist in the neighbourhood of many seas. Along the Firth of Forth, in Scotland, there is one very conspicuous about twenty-five feet above the present level of the sea, and which generally appears as a terrace at the base of a bank a few hundred yards back from the present shore. In the Firths of Clyde and Cromarty, and indeed in every place along the British coasts favourable for their preservation, similar beaches, from twenty-five to several hundred feet above the present sea-level,

can be traced. They may always be detected by their terrace-like level, and by the presence of rounded pebbles, gravel, sand, and in some instances sea-shells, such as usually compose beaches at the present day. In some places, old beaches have been conspicuous enough to become objects of popular wonder. In the vale of Glenroy, in Inverness-shire, as also in some neighbouring vales connected with Glenroy, there are three terraces along the sides of hills, at the successive heights

Terraces of Glenroy.

of 872, 1085, and 1165 feet, which the ignorant people of the district firmly believe to have been roads formed by the hero Fingal for hunting, but which are now shewn pretty clearly to have been the shores of quiet estuaries or arms of the sea, similar to many which still exist in the Scottish Highlands. Among the Alps, in Spain, France, Norway, in North and South America, and indeed in almost every region which has undergone a narrow inspection, there are vales marked in exactly the same way as Glenroy.

The existence of a force which *gradually elevates* the land in many places out of the water was discovered by Sir C. Lyell. His chief observations were made upon the shores of the Gulf of Bothnia, which he ascertained to have risen several feet in the course of the last century, and a few inches even since 1820.

Besides the greater elevating causes arising from subterranean fires, there are some lesser ones of less mysterious origin. The sands deposited on beaches are sometimes blown by winds in upon the land, covering the vegetable soil throughout a large space, and in some instances forming hills of considerable height and magnitude. Some parts of the coast of Holland are thus fenced with ranges of sand-hills, the whole mass of which has been blown back from the sea. On some parts of the French coast, large tracts, once smiling with cultivation, are thus buried under a sterile layer of sand, which is continually advancing, notwithstanding every effort of man. On the coast of Moray, in the north of Scotland, a district once forming the barony of Culbleen, has been transformed into a sandy tract since the fifteenth century.

In various parts of the world, new land is elaborated by the efforts of coral polypes. The works of these creatures are seen upon a vast scale in the Pacific, where whole ranges of islands are formed by them. On the coast of New Holland, there is a coral reef which stretches out to 1000 miles in length. The polypes do not commence their laborious operations at a great depth below water; from 60 to 100 feet is considered the utmost extent to which the coral extends downwards. Many of these islands are of a circular or oval shape; hence the opinion that corals build upon the rims and in the craters of submarine volcanoes. The outer wall of the building emerges first above the waves, enclosing a pool of tranquil water. The seeds of vegetables are either brought there by sea-birds, or wafted by the ocean, and the islands soon become clothed with a mantle of green. The substance of which these islands and reefs are composed is lime, which the polypes secrete from the sea-water, and cement together with a glutinous matter contained in their bodies. Sir C. Lyell, while surveying the Isthmus of Panama, detached a quantity of these animals, and placed them on some rocks in a shallow pool of water. On returning to remove them a few days afterwards, he found they had secreted stony matter, and had firmly attached themselves to the bottom. To such *organic* agencies of elevation as the coral animalcule, may be added the growth of shell-beds, the formation of peat, and other accumulating vital forces which contribute to the solid material of the earth's crust.

CHARACTERS AND POSITIONS OF ROCKS.

CLASSIFICATION.

It results from the various forces thus at work throughout a succession of ages, that some parts of the dry land are seen to be composed of crystalline or other rocks, of igneous origin, while others are strata—slaty, sandy, or limestone beds—which once constituted the bottoms of seas. Another readily traceable result is the change of most of the latter rocks from their original horizontal position to various degrees of inclination, and even to an entirely vertical arrangement, or to wavy and undulating forms. That one bed or set of beds should be mainly argillaceous in its character, and another sandy; or that one should be chiefly of quartz, while another is pure lime, has depended on various physical laws: as, for instance, a simple one causing light to be transported further than heavy materials; or else upon chemical laws, producing certain elections of materials out of watery solutions. Always, however, the rule holds good, that the inorganic materials of any sedimentary rock have been derived from the solid forms of rocks which previously existed. Each mass of aqueous origin, on its being elevated into dry land, has become a source of materials for new rocks. This brings us to the general fact, that there is a chronology in rocks. The uppermost of two beds is necessarily to be presumed as having been the latest formed. Accordingly, the order of *superposition* throughout the whole series, is also the order of *age*. If this be true of one bed lying *conformably* above another, it is still more strikingly inferred where, against one group of rocks tilted up at a high angle of inclination, there rest the edges of another group lying comparatively horizontal, as it then becomes evident that between the deposition of the two groups there had been an upheaving force at work, turning up the first formed beds. In general, the shapeless masses of the igneous rocks form mountains. Against these, rest the oldest sedimentary rocks, also assuming mountainous forms, and usually at high angles of inclination. Against these, in turn, more recent rocks usually rest *unconformably*, more horizontally, and composing lower and more level ground. Now, any one bed or group of beds may be wanting in particular districts; but whatever sedimentary rocks are *anywhere* present, they are *always* found in a determinate order, being that of their age.

An attendant circumstance is, that remains of plants and animals which lived in the seas where the rocks were formed, as likewise relics of other plants and animals which flourished on the neighbouring dry land, are imbedded, and to some extent preserved, in the rocks; forming so far a memorial of the state of life on the globe at each successive period which the rocks respectively represent.

In this exhibition of ancient life there are some remarkable general facts. None of the species, scarcely any of even the genera, now exist. There is a progress from humble to higher forms throughout the whole series, ending with mammalia, but excluding man. The earlier the age, the more widely diffused are particular species over the globe. The vegetable forms generally indicate a greater luxuriance than what now exists, and shew that certain lands had then a higher average temperature than they now enjoy.

The remains of certain species of mollusca and other marine animals being found in certain rocks, fossils come to be a means of ascertaining the position of rocks in the series.

In the accompanying figure, we see a mass of igneous and unstratified rock constituting a mountain, with a

Unstratified. Stratified.

series of sedimentary beds leaning against it in a position which shews that the rise of the mountain has tilted them up. Against their broken ends, again, rests a second and undisturbed series of beds. The line between the two sets of beds is a break of conformity; the later rocks are said to be *unconformable* to the older. Such breaks are generally regarded as marking periods of volcanic violence, when the surface underwent considerable changes. What had been for ages a sea-bottom, was then perhaps raised into the open air in a disturbed and distorted state, and possibly continued to be dry land for a series of ages. Afterwards sunk once more under the waves, new beds were formed upon or against it, containing, as usual, the remains of the plants and animals which existed at the time of their formation. It is evident that, if such a series of events took place, there was an interval of time with no representation of life—namely, that during which the lower mass of strata constituted dry land. Such really appears to have been the course of this strange history. After any great break of conformity, there is usually an extensive renewal of fossils, shewing that a long space of time had passed, during which organic life was considerably changed, but of which we have only this negative memorial.

A group of beds, starting from one point of non-conformity, and ending at another, constitutes what is called a *system*. It may be considered as chronicling the state of things on the surface of the globe during a particular era. There are thirteen or fourteen such systems, presenting in whole a great mass of positive knowledge respecting the ancient history of the globe, and yet leaving probably far larger spaces of time wholly unchronicled. Systems of strata are, again, massed into more comprehensive groups called formations, of which there are only three or four. To systems, the geologists of different countries give designations, usually taken from the name of some leading rock, as the old red sandstone or the coal, or else from the name of some province in their own country where the rocks of the system are conspicuous. Formations usually are designated as Primary, Secondary, Tertiary, or with a regard to the comparative antiquity of the life commemorated by them, as Palæozoic, Mesozoic, Cainozoic.

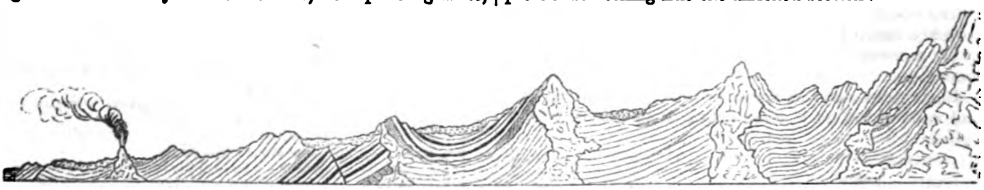
In the following table, the rock-systems recognised and described by English geologists are given, together with the more comprehensive groupings.

		SUPERFICIAL.	SOIL—decomposed vegetable and animal substances, with earthy admixtures.
			ALLUVIUM—deposits of sand, gravel, and clay, formed by the ordinary action of water.
			DRIFT (once called *Diluvium*)—a deposit of compact clay, mixed with boulders; the result of glacial action.
CAINOZOIC.	TERTIARY.		CRAG—calcareous conglomerate of marine shells and gravel; beds of marl.
			FRESH-WATER, OR ESTUARY BEDS—consisting of marls, imperfect limestones, and clays.
			MARINE BEDS—consisting of blue and plastic clays, thin beds of sand, lignite, &c.
MESOZOIC.	SECONDARY FORMATION.	*Chalk System.*	CHALK—soft and white, with layers of flint; chalk, hard, and without flints.
			GAULT, or beds of bluish marly clays, with green-sand.
			GREEN-SAND—beds of green ferruginous sands, with chert nodules.
		Oolitic System.	WEALDEN GROUP—beds of clay, argillaceous limestones and sands.
			OOLITE—beds of oolite limestone, calcareous grits, sands, and clays, all calcareous.
			LIAS GROUP—bluish clays, alum shales, marls, and limestones, all finely stratified.
		New Red Sandstone System.	SALIFEROUS MARLS—variegated shales and shell limestone, with bands of sandstone.
			RED SANDSTONE GROUP — fine-grained, sometimes conglomerate.
			MAGNESIAN LIMESTONE— thick-bedded limestones and calcareous conglomerates.
PALÆOZOIC.		*Carboniferous System.*	COAL-MEASURES—alternating beds of coal, shale, ironstone, and sandstone.
			MOUNTAIN LIMESTONE—thick-bedded, grayish limestones and shales.
			CALCIFEROUS SANDSTONES — white, thick-bedded sandstones, and calcareous shales.
		Old Red Sandstone System.	YELLOW SANDSTONES, with beds of mottled shales and marls.
			RED SANDSTONES—sometimes fine-grained, sometimes quartzose and conglomerate.
			GRAY OR RUSTY-COLOURED SANDSTONES—micaceous, and often in flags or thin-bedded.
	TRANSITION.	*Silurian System.*	LUDLOW ROCKS, generally argillaceous.
			AYMESTRY LIMESTONE.
			WENLOCK LIMESTONES AND SHALES.
			MAYHILL GROUP—sandstones.
		(*Lower Silurian?*)	CARADOC SANDSTONE.
			BALA LIMESTONE.
		Cambrian System.	ARENIG SLATE AND PORPHYRY.
			TREMADOC SLATE, LINGULA FLAGS.
			LONGMYND ROCKS.
	PRIMARY.	*Clay-slate System.*	CLAY-SLATE—finely laminated; dark, liver, and purplish coloured.
			HORNBLENDE AND CHIASTOLITE SLATES—finely laminated.
		Mica-schist System.	CHLORITE SLATES — greenish - coloured slates, with mica, mica-schist, talc-schist, crystalline limestone, and quartz rock.
		Gneiss System.	GNEISS ROCKS—intermingled with irregular beds of quartz rock, crystalline limestone, and mica-schist.

The reader must be guarded against supposing that the stratified rocks always occur in full and complete succession, as represented above: all that is meant is, that such as do anywhere occur are invariably in this order. Hence arises a practical maxim of great utility—namely, that *wherever any of these rocks occur, no example of those higher in the series is to be looked for at that spot.* At Durham, magnesian limestone occupies the surface; in Fife, the coal-measures; in Forfarshire, the old red sandstone. It would therefore be a waste of labour to dig for coal in Forfarshire, for oolite in Fife, or for chalk at Durham.

The unstratified or igneous rocks occur in no regular succession, but appear amidst the stratified without order or arrangement, heaving them out of their original horizontal positions, breaking through them in volcanic masses, and sometimes overrunning them after the manner of liquid lava. From these circumstances, they are in general better known by their mineral composition than by their order of occurrence. Still, it may be convenient to divide them into three great classes—*granitic*, *trappean*, and *volcanic:* granitic being the basis of all known rocks, and occurring along with the primary and transition strata; the trappean, of a darker

and less crystalline structure than the granitic, and occurring along with the secondary and tertiary rocks; and the volcanic, still less crystalline and compact, and of comparatively recent origin, or still in process of formation. This division of the igneous unstratified rocks subserves many useful purposes in geology, at the same time that it is a distinction warranted by the nature, aggregation, and aspect of their component minerals. The *granitic*, so named from their distinctly granular and crystalline texture, comprise granite, syenite, serpentine, porphyritic, and other varieties of granite. The *trappean* (Swedish, *trappa*, a stair) are so called from the step-like or terraced sides of the hills formed by these rocks, which include basalt, green-stone, clinkstone, trachyte, amygdaloid, &c. The *volcanic*, as the name implies, are those products discharged by recent or active volcanoes, such as lava, scoriæ, pumice, and tufa. As associated in the crust of the earth, the unstratified and stratified rocks would present something like the annexed section:



Tertiary. | *Secondary.* | *Transition.* | *Primary.*

In the above section, the UNSTRATIFIED ROCKS appear in hills and irregular disrupting masses, from the older granite to the active volcano; while the STRATIFIED occur in their regular order of succession. The *Primary* slope from the side of a lofty granitic mountain, at a high angle, and in bent or contorted strata; the *Transition* lie between the ranges of less elevated mountains; the *Secondary* occupy a still less elevated position, the Mountain Limestone being raised up on the hillside, with the Coal-beds thrown into basin-shaped hollows, or broken up by faults, and the Magnesian Limestone and Chalk rising up into slight eminences; the *Tertiary* in basin-shaped strata; and the *Superficial Accumulations* occur either as sandy downs by the sea-shore, or as drift, with boulders, overlying the earlier formations. The reader will perceive how the Tertiary strata are said to be above the Coal-measures, though they do not overlie them; and how the Coal-beds are above the Transition Rocks, though removed from each other by a wide extent of country.

ROCK FORMATIONS AND ORGANIC REMAINS.

PRIMARY.

Granite.—Granite may be described as an igneous rock, generally forming a basis or bed for all the other rocks—rising in some places from its unmeasured depths into chains of lofty hills—and in other places penetrating in veins through superincumbent rocks, and partially covering them. It composes a considerable portion of the mountain-ranges of Cornwall, Cumberland, Wicklow in Ireland, and the Scottish Highlands. The Alps, the Pyrenees, the Dofrefeld, the Abyssinian and other ranges in Africa, and the Andes in South America, are all more or less composed of rocks partaking of a granitic character.

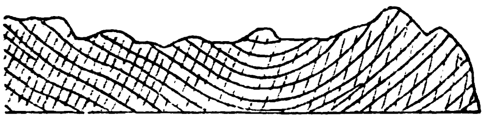
Three substances usually enter into the composition of granite—namely, 1. *Quartz* or silex, a whitish glassy substance, composed of oxygen in union with the metallic base, silicium; 2. *Felspar*, also a crystalline substance, but usually opaque, and coloured pink or yellow, composed of silicious and clayey matter, with a small mixture of lime and potash; 3. *Mica*, a silvery glittering substance, which divides readily into thin leaves or flakes, and consisting principally of flint and clay, with a little magnesia and oxide of iron. In some granites, instead of mica, we find *hornblende*, a dark crystalline substance, composed of alumina, silex or flint, and magnesia, with a considerable portion of the black oxide of iron. Such granites are called *Syenite*, from their abundance at Syene in Egypt. Other varieties are—*Serpentine*, in which there are dark spots like those on the skin of the snake (hence the name), and *Porphyry* (from its reddish colour), of which the distinguishing peculiarity is its containing little angular pieces of felspar enclosed in the mass. Any igneous rock containing such fragments, distinct from the common mass, is said to be *porphyritic*.

Primary Series.—Above the granite, in its ordinary position, lies a series of beds, consisting mainly of two kinds of rock—gneiss and mica-slate—with alternating strata of hornblende rock, quartz rock, eurite, talcose slates, chlorite slates, and argillaceous slates; of all of which it may be said that they follow no very determinate order. The lowest of these rocks are of the same materials as granite, in a very slightly modified form, and they are nearly as crystalline in their texture. Geologists also find in many places that the granite *passes* into them—a term expressing a blending of the characters of rocks at the line of their junction. Little room is left to doubt that the inferior stratified rocks were formed from the materials of the granite, disintegrated by mechanical or chemical means, and washed into the beds of vast seas, where, on their deposition, they were reached by the high temperature of the interior, and thereby reconsolidated in a crystalline form. To account for the rocks composed exclusively of one of the materials of the granite, we may suppose, as has been stated, some chemical separation of those materials.

The most prevalent rock of the series is *gneiss*, a compound, like granite, of quartz, felspar, mica, and hornblende, and so highly crystalline as to be sometimes scarcely distinguishable from granite. A great portion of the Highlands of Scotland is composed of strata of gneiss, of vast thickness. *Mica-slate* or *mica-schist*, the next most prevalent rock of the series, is composed of mica and quartz. It is the surface-rock of many extensive tracts of country. *Quartz rock*, which we may suppose to have been formed by a chemical separation of that component of granite, is also a prevalent rock. Humboldt takes notice of a mass of it in South America, more than 9500 feet in thickness. The round white pebbles or 'candy' stones, so often found on sea-beaches and in the beds of rivers, are pieces of quartz rock. *Eurite*, of which felspar is the main ingredient, and *hornblende* rock, the chief element of which is signified by its name, may also be accounted for by a chemical origin.

Clay-slate is the geological term for the well-known stone with which houses are roofed. It is, as its name imports, composed mainly of clay—a substance too liberally diffused amongst the ingredients of granite, to admit of any wonder as to its being found in a nearly distinct state in this rock. Mica-slate and clay-slate are *fissile* in their structure—that is, capable of being split into very thin plates: hence the utility of slate as a material for covering houses. But a curious diversity exists in this respect between mica-slate and roofing-slate. In the former, the *cleavage*, or direction in which it splits, is in the same line as the stratification; but in roofing-slate, the cleavage is always more or less transverse. What makes the latter circumstance the more remarkable—when strata of roofing-slate are found, as often happens, contorted or wavy, the direction of the cleavage is in one straight line through them all, indicating that the influence which produced the

cleavage in that rock took effect after the whole had been laid down, and after, by some subsequent accident of pressure, they had been forced into a wavy direction.



Section Exhibiting Lines of Cleavage in Clay-slate.

Probably this phenomenon owes its origin to electric or magnetic agency. Clay-slates are found in great abundance in Cornwall, Wales, Cumberland, and the Scottish Highlands. A fine kind makes the slates used at school, and from a kind still finer are cut the pens used for writing on school-slates.

In the *Primary* series there occur a few small beds of limestone, sometimes called *Crystalline* or *Saccharine Limestone*, from its resemblance to refined sugar, and sometimes *Primitive Limestone*, from the period of its occurrence in the series. In Greece and Italy, this rock has been subservient to the development of national talents, the highest that have ever been known of their class, for it is the marble from which the works of the Greek and Italian sculptors have been formed. In the geological history of our globe, its first appearance in the ascending series of rocks is an event of no small consequence; for limestone strata form a large proportion of the superior formations, and the manner in which they have been formed has engaged much attention. Limestone is the *carbonate of lime;* that is, a combination of the earth lime (itself a union of the metal calcium and oxygen) with carbonic acid (this being, again, a union of oxygen with the elementary substance carbon). Carbon is the largest element in the composition of vegetable and animal substances, and this its first appearance in the structure of rocks, is of course a point of much interest, more especially as it is generally concluded that many of the superior limestone strata have been entirely formed of animal remains. We are thus tempted to surmise that the formation of the primary limestone-beds marks some early and obscure stage of organic existence on the surface of our planet. No distinct remains of plants or animals have indeed been found in the series; and it is customary to point to the next upper series, in which both do occur, as the dawn of organic life. Yet many geologists are of opinion that the primary rocks might have contained such remains, though the heat under which the rocks seem to have been formed may have obliterated every trace of such substances. This series constitutes in most regions the great depository of the metals—gold, silver, tin, copper, &c.—which occur in irregularly intersecting veins, composed of ore-stone differing in composition from that of the containing strata. (For opinions as to the origin and character of metalliferous veins, we must refer to the article—METALS AND METALLURGY.)

TRANSITION.

Cambrian and Silurian.—All the rocks hitherto described are of crystalline texture, and, apparently, chemical phenomena have attended their formation. In the group now arrived at, we see little besides the traces of mechanical origin and deposition; but still a few strata resembling the preceding occur throughout the lower parts of this series, as if the circumstances under which the earlier rocks were formed had not entirely ceased. Hence the term *transition*, as implying a passing from one state of things to another.

The rocks forming the lower part of this group—termed *Cambrian* from their forming a large part of the surface of Wales—are an alternation of beds of chlorite, talcose, and other slates, resembling those of the primary series, with beds of clayey and sandy rock, of apparently mechanical origin, and thin beds of limestone, in which a few fossils are found. It thus appears that the cessation of the chemical origin of rocks, and the commencement of organic life, are events nearly connected; and it has thence been surmised that the temperature of the earth's surface was now for the first time suitable to the production and maintenance of organic things. At the same time, the alternation of the rocks teaches us the instructive fact, that the change was not direct or uniform, but that for some time the two conditions of the surface superseded each other. This is conformable with a general observation which has been made by Sir H. De la Beche—namely, that however sudden changes may have taken place in particular situations, a general change of circumstances attending rock formations is usually seen to have been more or less gradual. The few fossils found in this part of the series are, as far as ascertained, the same, or nearly so, as those of the superincumbent Silurian.

The Silurian group—so called from its being very clearly developed in that district of country between England and Wales which was inhabited by the ancient *Silures*—consists of arenaceous and slaty rocks, of evidently mechanical origin, intermixed with numerous beds of limestone and calcareous shales. The general composition of the series indicates its having been formed of a fine *detritus* (matter washed from other rocks), and its having been deposited slowly; although, as in the case of the inferior group, the arenaceous beds occasionally pass into coarse conglomerates. The limestones are less crystalline than those of the primary series; the arenaceous beds are also less silicious, and more closely resemble ordinary sandstones; while the abundance of organic remains justifies their arrangement into a separate system.

The lower transition rocks form the immediate surface in many large districts in Scotland, England, France, Germany, and North America, shewing that at the time of their formation 'some general causes were in operation over a large portion of the northern hemisphere, and that the result was the production of a thick and extensive deposit, enveloping animals of similar organic structure over a considerable surface.' The igneous rocks associated with the transition series are chiefly granitic; effusions of trap making their appearance only among the later strata. Perhaps the most extensive and gigantic efforts of volcanic power were exhibited at the close of this period; and there is abundant proof that all the principal mountain-chains in the world were then upheaved. The Grampian and Welsh ranges, the Pyrenees, Harz Mountains, Dofrefeld, Uralian, Himalaya, Atlas range, Mountains of the Moon, and other African ridges, the Andes, and Alleghanies—all seem to have received their present elevation at the close of the transition period.

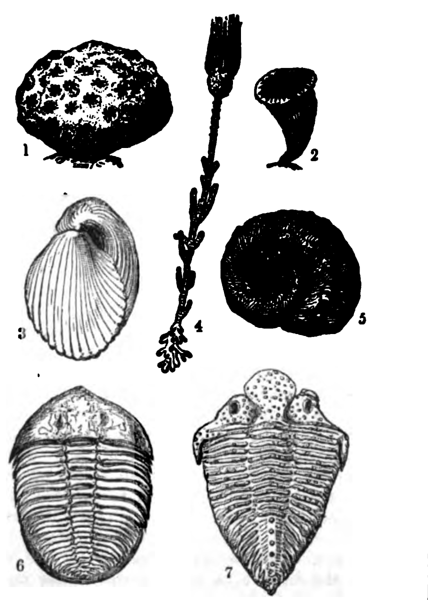
Transition Fossils.—If we are to judge of the organic life of this early period from the evidence of the fossils actually as yet discovered in its strata, we should say that it was of a comparatively humble kind. Throughout an immense range of its rocks, below the highest, there are no appearances of fresh-water or land plants, and none of vertebrate animals. In the Cambrian rocks, as limited by Sir R. I. Murchison to those below the Bala limestone, only one or two polypes, mollusks, and crustacea have been as yet, and these very recently, found. In the Bala, Caradoc, and Wenlock rocks, no true examples of fish have been discovered. That vertebrate form makes its first appearance in the Ludlow rocks.

There is a great break in the character of the fossils between the Caradoc and Mayhill rocks, greater in America than in England; and hence the opinion of some geologists that the Bala and Caradoc should be regarded as not Lower Silurian, but as Cambrian. Taking, however, the whole range as Silurian, Lower and Upper, what is the character of life presented? It is exclusively marine. The plants are a few algæ; the

animals are marine, and, excepting at the top of the series, invertebrate.

There is abundance of those creatures (*polypi*) resembling plants, which fix themselves on the bottom of the sea by stalks, and send forth branch-like arms for the purpose of catching prey, which they convey into an internal sac, and digest. At present, these creatures abound in the bottoms of tropical seas, where they live by devouring minute impurities which have escaped other marine tribes, and thus perform a service analogous to that of earthworms and other land tribes, the business of which is to clear off all decaying animal and vegetable matter. But the class of animals found in greatest numbers in this series of rocks are mollusks, possibly because the remains of these creatures are peculiarly well adapted for preservation. Among the radiata or rayed animals, the *crinoid* or *encrinite* family occur for the first time, these differing from other corals in the self-dependent nature of their structure, their fixed articulated stalk and floating stomach, furnished with movable rays for the seizure and retention of their food. As we ascend in the Silurian group, the shell-fish become more numerous and distinct in form; *spirifers*, *terebratulæ*, and *productæ*, are everywhere abundant; and *cephalopoda*, like the existing nautilus, begin to people the waters. These last were the chief destructive animals of the period—the police which kept down the swarms of lower life around them. Some of them were of gigantic magnitude, and, with their tenacious wide-spreading tentacula, must have been truly formidable creatures. It is nevertheless to be remarked, that the cephalopoda of this epoch are of a lower grade of structure than those which afterwards came into existence.

Of the crustacea of this era, the most interesting and abundant type is the *trilobite* (three-lobed), of which several genera and many species have been described, and to which scarcely any existing creature bears an analogy. The trilobite (see fig.) was a true crustacean,



1. Astrea; 2. Turbinolia Fungites; 3. Leptæna Lata; 4. Actinocrinites; 5. Euomphalus Rugosus; 6. Trilobite—Asaphus de Buchii; 7. Trilobite—Asaphus Tuberculatus.

covered with shelly plates, terminating variously behind in a flexible extremity, and furnished with a head-piece composed of larger plates, and fitted with eyes of a very complicated structure. It is supposed by some to have made its way through the water by means of soft paddles, which have not been preserved; and by others, merely to have sculled itself forward by the aid of its flexible extremity. Of its various organs, the most interesting is the eye, of which several specimens have been obtained in a very perfect state. This organ, according to fossil anatomists, is formed of 400 spherical lenses in separate compartments, on the surface of a cornea projecting conically upwards, so that the animal, in its usual place at the bottom of waters, could see everything around. As there are two eyes, one of the sides of each would have been useless, as it could only look across to meet the vision of the other; but on the inner sides there are no lenses, that nothing may, in accordance with a principle observable throughout nature, be thrown away. It is found that in the serolis, a surviving kindred genus, the eyes are constructed on exactly the same principle, except that they are not so high, which seems a proper difference, as the back of the serolis is lower, and presents less obstruction to the creature's vision. It is also found that in all the trilobites of the later rocks the eyes are the same. This little organ of a trivial little animal carries to living man the certain knowledge that, millions of years before his race existed, the air he breathes, and the light by which he sees, were the same as at this hour; and that the sea must have been in general as pure as it is now. If the water had been constantly turbid or chaotic, a creature destined to live at the bottom of the sea would have had no use for such delicate visual organs.

A few fragments of fish, ascribed to four species, named *onchus*, *plectrodus*, &c., occur in the Ludlow rocks, forming, as it were, a dawn to the full development of this class of animals in the next rock system.

LOWER SECONDARY.

The Old Red Sandstone System, as indicated by the name, is chiefly arenaceous, presenting a succession of sandstones alternating with subordinate layers of sandy shale. The sandstones pass, in fineness, from close-grained fissile flags to thick beds of conglomerate, the latter being composed of pebbles from the size of a hazel-nut to that of a man's head. The whole system is tinged with the peroxide of iron, the colours ranging from a dark rusty gray to brick-red, and from a mottled purple and fawn shade to a cream-yellow. There are some calcareous beds in the system; but these are not regularly developed, and are all silicious and concretionary in their composition and texture. Taken in the mass, the composition of this system is sufficiently indicated by the term *old red sandstone*—the epithet 'old' being applied to distinguish it from another series of red sandstones which occurs above the coal-measures, and is usually designated the *new red sandstone*.

The development of this system in a district of Western England has occasioned its receiving the subordinate name of *Devonian;* but it is much more largely exhibited along the east coast of Scotland, around the primitive rocks forming the Highlands. The laminar sandstones quarried at Arbroath and in Caithness for various useful purposes, are a noted portion of the system.

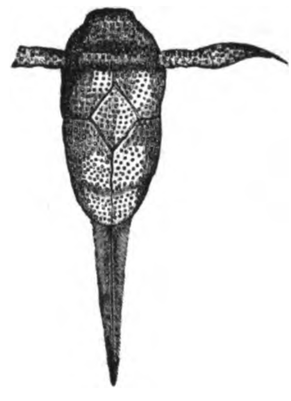
The Devonian fossils comprise an abundance of zoophytes and mollusks. The crustacea are diminished. Fishes come in great numbers upon the scene. In an upper bed, the remains of a reptile have been found, being the dawn of that superior order. The fishes form the most remarkable feature of the system. Nearly a hundred species are described, all being of the cartilaginous order, and therefore of a lower developmental type than the orders which afterwards came into existence. There is, however, much to engage attention in the curious external plates which in them make up for the softness of the skeleton.

One remarkable group, at first sight, resemble crustacea more than fishes. The internal skeleton has been so slight, that no trace of it has ever been found. To

make up for this weakness of internal framework, the surface of the body has been entirely covered with bony plates. Three remarkable forms, one comprising wing-like appendages, are here depicted.

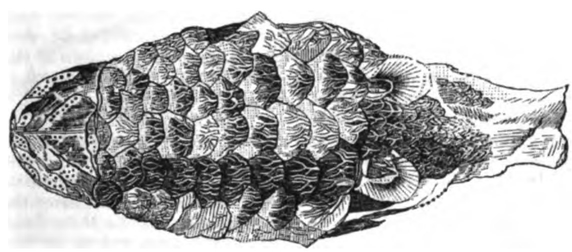
Cephalaspis.

Coccosteus.



Pterichthys.

In the *holoptychius* and some others, the bony covering is formed of a greater number of plates, finely enamelled and curiously sculptured, while the general outline more closely approximates to that of the existing fishes. In



Holoptychius Nobilissimus.

other genera, the plates pass by gradations into bony scales, regularly arranged so as to join or overlap each other. This structure is well illustrated by the *osteolepis*, which presents the form of a perfect fish, furnished with pectoral, abdominal, and caudal fins. Some families of these early fishes are furnished with spiny fins, or are otherwise armed with detached spines from two to five inches in length, and which are known to geologists by the term *ichthyodorulites*.

Carboniferous System.—This is a very extensive system, comprehending not only the coal-measures proper, from which it takes its name, and which consists of alternating strata of coal, shales, sandstones, ironstones, &c., but embracing also the mountain limestone, which always underlies the coal group, and which, in turn, comprehends alternations of limestone, shales, sandstones, and imperfect coal-beds.

Mountain Limestone—so called from its being generally found flanking or crossing the trap-hills which intervene between the old red sandstone and the coal-measures—is an abundant rock. It is frequently traversed by beautiful veins of calcareous spar, and many valuable veins of lead-ore are associated with it in Britain and elsewhere. It is of various colours, but mostly gray, varying in intensity of shade. Its associated rocks are principally calcareous sandstones and shales, abounding in organic remains, corals, encrinites, &c., which point to a marine origin.

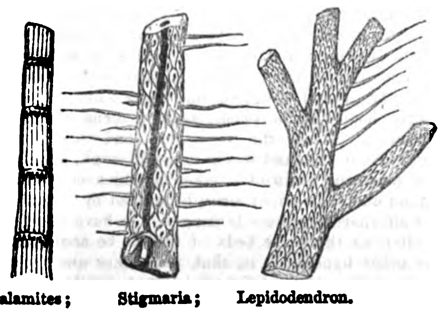
The superior group more particularly called *Carboniferous*, and variously termed the *Coal-measures*, is composed of beds of that mineral, often very numerous, alternating with beds of sandstone, shale, limestone, ironstone, and some other substances. As many as forty beds of coal exist in the neighbourhood of the town of Newcastle. The great utility of this mineral as a domestic fuel, and in the arts, gives it a high importance; and happy is the country in which it exists in any considerable quantity. In a merely geological point of view, it is equally important. This rock is entirely a mass of vegetable matter, which has accumulated in certain situations, and afterwards been covered over, pressed upon, and converted by bituminous fermentation into several varieties of coal.

Two hypotheses have been advanced respecting the circumstances under which coal was formed. According to one, the vegetable matter must have grown in dense forests and jungles for many years; then the land must have sunk, and become the basin of a lake or estuary, in which situation rivers would wash into it mud and sand, which would cover over the vegetable mass, and form superincumbent beds of shale and sandstone respectively. Then the ground would be once more elevated, or sufficiently shoaled up to become again a scene of luxuriant vegetation. When the vegetation had again become accumulated, the land would be again sunk, and become once more the basin of a lake, in which case the beds of mud and sand might again be formed by rivers. And this alternating process is supposed to have taken place as often as there are beds of coal to be accounted for. The other hypothesis is, that, into lakes and estuaries, rivers coming from different quarters would bring the various matters forming the strata of the carboniferous group—a river from one direction bringing the mud which would form shale, another from another direction the vegetable matter which would form coal, and so on,

each deposit perhaps taking place through the efficacy of some local circumstances, while the causes for the other deposits were temporarily suspended. Both theories are beset with difficulties, and perhaps the true solution is to be found in a combination of the two. Estuary and lake deposits, inundating rivers, a high temperature, a prolific Flora, and frequent elevations and subsidences of the land, seem to have been the conditions under which the coal-measures were deposited.

Fossils of the Carboniferous Group.—In this group of rocks several hundred species of plants have been discovered, all of them now extinct. About two-thirds of them are ferns; the others consist of large *coniferæ* (allied to the pine), of gigantic *lycapodiaceæ*, of species allied to the *cacteæ* and *euphorbiaceæ*, and of palms. Most of these plants probably exist in the coal-beds, forming, in fact, their sole composition; but the peculiar nature of this mineral renders it difficult to detect them by examination. Thin slices, however, have been examined by the microscope, and the vegetable structure has then been detected where no external trace of it was visible. In cannel-coal, a kind peculiarly compact, the vegetable structure is observed throughout the whole mass, while the fine coal retains it only in small patches, which appear, as it were, mechanically entangled. Splint and cannel coal often bear distinct impressions of plants. The plants are such as grow in hot moist situations; and it is therefore presumed that a climate of that nature existed at an early period where coal is now found, even in Melville Island, which is within the polar circle.

Large fragments of trees are often found in the shale and sandstone beds of the carboniferous group—more frequently in the former than in the latter. As usual with fossil substances, they are converted into the material in which they are imbedded, but preserve all their original lineaments, except that they are generally changed from their original round to a flattened form, the result of the pressure they have sustained. In most instances, these fragments of trees appear to have been transported from a distance, and laid down horizontally in their present situation; but some have been found with their roots still planted in their native soil of mud, and the stems shooting upwards through several superior beds of various substances. Even in some coal-beds there are found stems of trees in their original vertical position—the roots being imbedded in shale beneath. In these instances we must suppose the fossil to be on the spot where the living tree sprung, grew up, and died. In the Bensham coal-seam in the Jarrow coal-field, a few years ago, there was found an upright tree of the kind called lepidodendron, thirteen and a half feet wide at the base, and thirty-nine feet high, the branches at the top being also entire: the lepidodendron is so called from the scaly appearance of its stem, the scales being the roots of the leaf-stalks (see fig.). Various fossil trees have been discovered in

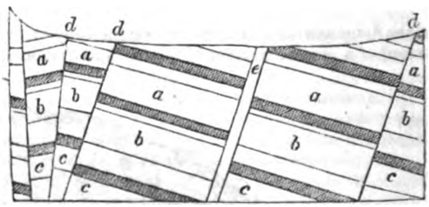


Calamites; Stigmaria; Lepidodendron.

the sandstone-beds of the carboniferous group at Craigleith and Granton, in the county of Edinburgh. One found in Craigleith Quarry was twenty feet long, three feet in diameter, with scars where the branches had been torn off, and was ascertained, by microscopic inspection of slices of the trunk, to have been a conifera, of the existing genus *Araucaria*.

The animal remains of the carboniferous group consist of zoophytes (corals, encrinites, &c.) in vast profusion, of shell-fish, crustacea, and fishes. In the mountain limestone the crinoidea seem to have attained their meridian, for whole beds, many feet thick, and square miles in extent, are almost wholly composed of them; hence the not unfrequent term *Encrinital Limestone*. Shell-fish, univalve, chambered, and bivalve, also abound; the trilobite, and crustacea allied to the modern *chiton*, are by no means uncommon; and fishes of a gigantic size and sauroid structure are scattered throughout the strata both of the mountain limestone and the coal-measures.

Intimately connected with the carboniferous system, are numerous intrusions of igneous rocks, shewing that it was an era of much volcanic disturbance. The sedimentary beds are from this cause much broken up and dislocated, as may best be comprehended by a study of the annexed figure. Here *d*, *d*, *d*, indicate what are called *slips* or faults; *e* is one of these containing an



Dislocations of Coal strata.

intrusive vein or *dike* of trap; while the other letters shew the original relations of the strata now torn away from each other.

New Red Sandstone System.—This series of strata, lying above the carboniferous system, comprehends rocks called the *red conglomerate*, formed of pieces of earlier rocks, some rough, some smoothed by rolling, all caked together; *magnesian limestone*, abounding in Germany and the north of England; *red* or *variegated sandstone*, a group of many varieties of colour, and principally of argillaceous and silicious consistence; *muschelkalk*, a limestone varying in texture, but most frequently gray and compact—not found in Britain or France, but occurring in Germany and Poland; and *variegated marls*—beds of different colours, red, blue, and gray, composed of the remains of shell-fish.

To these also belong beds or masses of *rock-salt*, of which many exist in England, particularly in the county of Chester. Rock-salt is a crystalline mass, forming irregular strata, sometimes of the thickness of several hundred feet. It is believed to be the residuum of evaporated estuaries. The substance is rarely pure, but generally contains some portion of argillaceous oxide of iron, which gives it a red colour. It is dug like coal and other minerals, and when dissolved and subjected to proper purification, is sold for domestic purposes.

Fossils of the New Red Sandstone Group.—The vegetable remains of this group belong to the same families as those of the coal strata, only they are found very sparingly and of diminished dimensions; but in the department of animal life, when we arrive at the muschelkalk or shell-limestone, we find a great difference, leading to a supposition that at this era of geological chronology circumstances had arisen changing the character of marine life over certain portions of Europe; that certain animals abounding previously, and for a great length of time, disappeared never to reappear, at least so far as we can judge from our knowledge of organic remains;

and that certain new forms of a very remarkable kind were added.

The new creatures were of such a class as we might expect to be first added to the few specimens of fish which had hitherto existed: they were of the class of Reptiles—creatures whose organisation places them next in the scale of creation to fish, but yet below the higher class of animals which bring forth their young alive and nourish them by suck (mammalia). The reptiles, which first begin to appear in the muschelkalk, continued to flourish while a great succession of other rocks was in course of deposit: throughout the whole of the Secondary Formation there were few other land-animals.

UPPER SECONDARY.

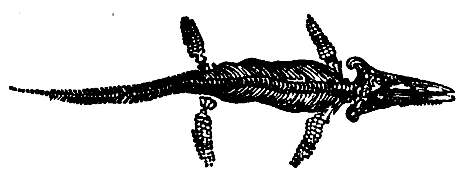
Oolitic System.—After the deposition of the new red sandstone, a further change was effected upon the general conditions of the globe, so as to produce not only an entirely different set of strata, but also different races of plants and animals. In most districts, the red sandstones and magnesian limestone were upheaved, to form new land, while portions of the former dry land were submerged beneath the ocean. By this process of elevation and depression the courses of previous rivers would be altered, former seas circumscribed and rendered more shallow, plants and animals subjected to a new distribution, and thus a different set of deposits would necessarily ensue. Instead of magnesian rocks we have dark argillaceous and oolitic limestones; for variegated saliferous marls we have blue pyritous clays; and instead of red and mottled sandstones, yellow calcareous grits. All this points to a new epoch in the terrestrial conditions of the world; and to the system of strata thus deposited geologists apply the term *oolitic* (Gr. *oon*, an egg, and *lithos*, a stone), from the resemblance which the texture of many of the beds bears to the roe or eggs of a fish. The system in England comprises three well-defined groups; namely, the Lias, the Oolite proper, and the Wealden clays—all of which are less or more developed in other parts of the eastern hemisphere.

The *Lias*, the lowest group in the system, is composed of dark argillaceous limestones, bluish clays, and shales. As indicated by the name (*lias*, corruption of *layers*), the limestones are finely stratified, and have evidently been deposited in tranquil waters. The *Oolite* is more varied in its composition, consisting of oolite limestones, calcareous conglomerates, yellowish sands and clays, all more or less calcareous. The peculiar rounded grains which constitute the oolitic texture consist either entirely of lime, or of an external coating of lime collected round minute particles of sand, coral, shells, &c.; the grits are composed of sand, lime, fragments of shells and corals; and many of the clays present the same brecciated texture. The *Wealden group* (from the *wealds* or *wolds* of Kent and Sussex, where the deposit prevails) consists of beds of bluish clay, argillaceous limestones, impure oolites, and ferruginous sandstones. Fossil plants are abundant; and, as may be expected from this circumstance, local traces of coal are not unfrequent.

The *organic remains of the Oolitic system* are very numerous, and have long attracted the attention of geologists. They shew a decided advance upon pre-existing races, inasmuch as insects, amphibious reptiles, and mammalia make their appearance in the Animal Kingdom; while new tribes of vegetables, such as the cycadeæ, liliaceæ, &c., are added to the former Flora. The organisms of the lias, the oolite, and the lower members of the wealden, indicate the marine origin of these deposits; those of the upper weald an estuary character, from the comminglement of fresh-water with marine species. With this distinction, the Fauna and Flora of this epoch may be thus summarily detailed:—*Plants*—sea-weeds; a few equisetums; many ferns allied to those of the coal-measures; cycadeæ allied to the existing cycas revoluta and pine-apple; coniferæ resembling the yew and pine; besides liliaceæ and other undescribed genera. *Animals*—zoophytes, more like existing species than those of the mountain limestone and silurian rocks; crinoidea, chiefly the pear-shaped encrinite pentacrinite; star-fishes resembling the common ophiura and asterias; echinida (sea-urchins), of which the cidaris is one of the most beautiful and abundant; shell-fish, both bivalves, univalves, and chambered; annulosa like the common serpula and land-worm; crustacea resembling the lobster tribe; insects like the beetle and dragon-fly; fishes, chiefly with enamelled scales; reptiles allied to the tortoise, to the crocodile, and gavial of existing rivers, but differing widely in their external forms and modes of existence; mammalia, two or three specimens of small marsupial animals allied to the opossums, and one bird. In the upper or fresh-water wealden there are no zoophytes or marine mollusca; but there are, according to Phillips, various land-plants, fresh-water bivalves and univalves, some fishes, sauroid animals, and remains of turtles, both fresh water and marine.

The reptiles of this early age were peculiar both in size and in structure. Some, which inhabited the seas, resembled lizards, but were of gigantic size; others, designed for land as well as sea, resembled the crocodiles which still exist in warm climates.

One of the most remarkable kinds (genera) has received the name of *Ichthyosaurus* (Fish-lizard), of which seven species or varieties have been discovered. The head is like that of the crocodile, composed of two long slender jaws, provided with a great number of teeth (in some cases 180), and eyes of great size (in one



Skeleton of the Ichthyosaurus.

instance, the cavity for the eye has been found to measure fourteen inches), while the nostril, instead of being near the snout, as in the crocodile, was near the anterior angle of the eye. The body was fishlike, arranged upon a long spiral column, which consisted of more than 100 joints, and to which a series of slender ribs was attached, and terminating in a long and broad tail, which must have possessed great strength. The whole length of some specimens of the ichthyosaurus was about thirty feet. Instead of the feet with which the lizard and crocodile are furnished, the ichthyosaurus had four paddles like those of the whale tribes, fitting it to move through the waters in the manner of those animals. It had also a construction of the sternum or breast-arch, and of the four paddles, similar to that found in the ornithorhynchus, an aquatic quadruped of New Holland, and evidently designed, as in the case of that animal, to enable it to descend to the bottoms of waters in search of food. While the ichthyosaurus, then, is mainly allied to the lizard tribes, it combined in itself the additional characters of the fish, the whale, and the ornithorhynchus.

The internal structure and the modes of living of the ichthyosaurus have been in a most unexpected manner made clear by the discovery of the half-digested remains of animals found within them or in their neighbourhood. It appears that the creature possessed a large stomach, extending throughout nearly its whole body, and that it lived upon fish and other reptiles, including its own kind. It must have occasionally devoured creatures several feet in length. Masses of the excrement of the ichthyosaurus, petrified as hard as the finest marble, and well known to geologists under the name of

coprolites (literally, dung-stones), are found to be marked spirally, like the voidings of certain species of sharks and dogfish, the intestinal gut of which winds greatly, in order that it may take up the least possible room. We thus obtain a distinct idea of the nature of a very important part of the bodily economy of this long extinct race of animals. The stomach occupied so large a space in their bodies for the reception of large quantities of food, and it was at the same time so necessary that the speed of the animal in pursuit of prey should not be clogged by a very large or long body, that the smaller intestines had been, by a wise arrangement of nature, reduced nearly to the state of a flattened tube, coiled like a cork-screw around itself; 'their bulk being thus diminished,' says Buckland, 'while the amount of absorbing surface remained nearly the same as if they had been circular.'

The name *Plesiosaurus* is applied to another highly remarkable reptile of gigantic size which inhabited the world before the days of mammalia. A particular species has been described as having a body and paddles which bore some resemblance to those of the ichthyosaurus, the former being more bulky, and the latter longer and more powerful. At the end of a long neck, like the body of a serpent, was a head resembling that of a lizard, but also partaking of the characters of the head of the crocodile and ichthyosaurus. The tail was short. The backbone of this creature, and the neck and tail continuing it, contained in all about ninety vertebral pieces, thirty-three of which composed the neck; and the vertebræ are found to be of a less fishlike structure than those of the ichthyosaurus, and not nearly so well calculated for rapid motion. The plesiosaurus probably lived chiefly on or near the surface of the water, breathing the air, and dabbling for prey like a duck or swan, but might also be able to descend to the bottom, and even to move, though awkwardly, upon land.

Of the crocodile family, found in abundance in this class of rocks, the *Iguanodon* may be cited as a specimen. It was a huge animal, resembling the present iguana of South America, which chiefly lives upon plants and seeds. The smallest part of the thigh-bone of an iguanodon was found to be twenty-two inches in circumference, and much larger than that of any existing elephant. Species resembling the present gavial of the Ganges have also been found. It may fairly be inferred from the present habits of the gavial and other kinds of crocodiles, that at the time when the extinct species flourished, the world must have contained many low shores and savannas, fitted for the residence of such creatures. Some parts of England are thus proved to have had at one time shores of lakes and estuaries resembling those of the Ganges, the Nile, and other waters in hot countries, and consequently a much higher temperature than at present.

But perhaps the greatest wonder of the reptile age was the creature called the *Pterodactyle*. Mainly a reptile of the lizard kind, its body possessed some of the characteristics of the mammalia: it had the wings of a bat, the neck of a bird, and a head furnished with long jaws, full of teeth, so that in this last part of its organisation it bore some resemblance to the crocodile. Eight species of the pterodactyle which have been found vary from the size of a snipe to that of a cormorant. The eyes were of enormous size, apparently enabling it to fly by night. From the wings projected fingers, terminated by long hooks, like the curved claw on the thumb of the bat. These must have formed a powerful paw, wherewith the animal was enabled to creep or climb, or suspend itself from trees. It has been conjectured that the pterodactyle would chiefly live on flying insects, of which, it is important to notice, several varieties existed at the same time, their remains being found in the same rocks. And it is likely, from the size of the eyes, that it searched for prey by night as well as by day. But it has also been argued, from the great length and strength of the jaws, and the length of the neck, that the pterodactyle did not live solely upon flies, but likewise sought for fish in the manner of our own present sea-birds.

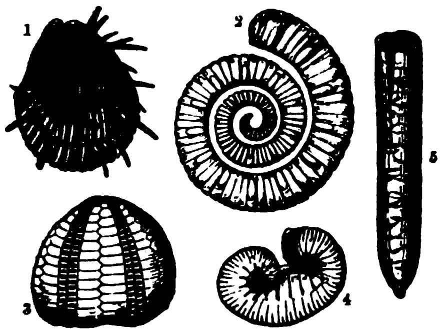
Tortoises also existed during this and the preceding age, as is proved by the marks of their feet (technically, *Sauroidichnites*) on beds of sandstone, as well as by their remains. As yet, few animals of a higher class had appeared upon earth—the remains of certain creatures of the Opossum family, found in the oolite at Stonesfield near Oxford, exhibit at the utmost the dawn of mammalian life. With, then, flocks of pterodactyles flying in the air in pursuit of huge dragon-flies; gigantic crocodiles and tortoises crawling amidst the jungles of low, moist, and warm shores; and such monsters as the ichthyosaurus and plesiosaurus swarming in estuaries; while the waters of the ocean were peopled by infinite varieties of fish; we can form some faint idea of what sort of world it was while the strata between the coal and the chalk formations were in course of being deposited.

Cretaceous or *Chalk System*.—Immediately overlying the wealden, and forming the upper portion of the secondary formation, occurs a set of calcareous, argillaceous, and arenaceous strata, distinguished in Europe as the Cretaceous System, from its containing the well-known mineral *chalk* (Lat. *creta*). In this system the arenaceous members are no longer sandstones, but loose unsolidified sands; the argillaceous beds are generally soft and marly clays; and the calcareous, instead of compact or crystalline limestones, present that soft earthy texture which prevails in chalk. All this attests a comparative recentness of formation, apart from great pressure, long-continued chemical action, or the indurating effects of heat. The strata occupy very limited spaces, and being decidedly of marine origin, point more to detached and inland seas as the areas of their deposit than to the shores or bays of the ocean. Being thus, as it were, a local deposit, and of a thickness not exceeding 800 or 900 feet, the chalk has been more thoroughly explored than any of the older systems, and its fossils more rigidly compared with existing species. Upon investigation it has been found that it embraces three well-marked groups—namely, the *Green-sand*, the *Gault*, and *Chalk*.

The *Green-sand*, which forms the lower division, is so named from its prevailing green colour, which it owes to a chloritous silicate of iron. In England, they are usually divided into the Lower and Upper green-sands, because of a bed of soft bluish marly clay which occurs about the middle of the group. The *Gault* or *golt* (a local term) overlies the green-sand, and is not of great thickness, nor very regular in its occurrence. It is a bluish chalky clay, interstratified with layers of green-sand, and holds irregular balls of clay, ironstone, and iron pyrites. The *Chalk*, which forms the upper group of this system, is too well known to require description. It consists chiefly of carbonate of lime, has an earthy texture, and is so soft as to yield to the nail. Though generally white, it sometimes passes into a dusky gray, or even red colour; and where it has come in contact with igneous rocks, it is indurated, and of a crystalline texture, like that of statuary marble. In England, the chalk strata average from 600 to 800 feet in thickness, and are usually divided into the lower and upper beds; the former being more compact, of a dusky white, varied with green grains, and containing few flints—the latter being a soft white calcareous mass, with chert nodules and regular layers of flints. Traces of stratification are scarcely distinguishable in the mass of the chalk, but are clearly evinced by the lines of flints and other nodular concretions.

The organic remains found in the system are eminently marine. There are very few *plants*, and these chiefly of marine types, such as algæ, confervæ, and other sea-weeds. Rare fragments of ferns, cones of coniferous trees, cycadites, and dicotyledonous wood, have been

detected in the green-sand; but, generally speaking, there is no formation so destitute of terrestrial organisms as the chalk. Among the *animal remains*, sponges, corals, star-fishes, annulosa, univalve, bivalve, and chambered mollusca, crustacea, fishes, and reptiles, are found in abundance; but, with one exception, mammalia are not known in the cretaceous rocks. The same races which appeared in the oolite, appear also in the chalk, but of very different genera; so much so, that it has been observed that the cretaceous system contains genera never found in any rocks more ancient or more modern. The following are characteristic fossils:



1. Plagiostoma spinosum; 2. Hamites intermedius; 3. Galerites albogalerus; 4. Scaphites striatus; 5. Belemnites mucronatus.

TERTIARY.

The Tertiary Formation comprises all the *regular strata* of limestone, marl, clay, sand, and gravel, which occur above the chalk. Before the labours of the celebrated Cuvier and M. Brogniart, these beds were regarded as mere superficial accumulations, not referrible to any definite period. Now, however, they are recognised as constituting a distinct formation—differing, on the one hand, from the cretaceous, not only in its mineral composition, but in the higher order of organisms which it contains; and on the other, from the superficial sands and clays, in being regularly stratified, and in imbedding the remains of animals distinct from existing races. In general, the strata are loosely aggregated, are of no great thickness, and present appearances which indicate frequent alternations of marine and fresh-water agencies. Thus marine remains are found in some beds, while others contain exclusively land animals and plants, and fresh-water shells. The whole suite being less consolidated than any of the secondary systems, and containing plants and animals approaching to existing forms, it presents a freshness of aspect which serves to distinguish it from older deposits; at the same time the regularity of its deposition prevents it from being mistaken for any mere alluvial accumulation. In general, it occupies very limited and detached areas, as if it had been formed in shallow inland seas and estuaries to which the waters of the ocean at times had access, and where at other periods fresh-water inundations prevailed. Another essential difference between the tertiary and the more ancient formations consists in the fact, that the latter maintain a wonderful uniformity in their composition and character all over the globe; whereas the former present almost as many distinctions in composition as there are areas of deposit. For this reason it is impossible to give a description applicable to all tertiary strata; those of England and France, however, may be taken as types sufficiently characteristic.

The following is a descending section of the Paris basin, according to Cuvier and Brogniart:

5. Upper Fresh-water Group—marls, marly sands, shelly limestone, and silicious or *burr* limestone.
4. Upper Marine Group—marls, sands and sandstones of a white or ochraceous colour, and loosely aggregated; thin layers of limestone.
3. Lower Fresh-water—marls, gypsum (sulphate of lime,) with bones of animals, and silicious limestones.
2. Lower Marine—consisting principally of a coarse sandy limestone (*calcaire grossier*), with calcareous marls and layers of greenish sand.
1. Plastic Clay Group—consisting of bluish plastic clays, with layers of sand, beds of lignite, and rolled pebbles. Supposed to be of estuary origin.

Although a very different succession takes place among the tertiaries of the south of England, yet there is sufficient resemblance in the position and aggregation of their strata, as well as in their organic remains, to establish the fact that they belong to the same epoch as the rocks of the Paris basin. The annexed section shews the order of their occurrence to the south of London:

4. Bagshot Sands.
3. London Clay—of a dull gray, or blue, or ochraceous colour; often full of green grains. Septaria and other ferruginous nodules occur in some parts. Numerous fossils.
2. Plastic Clay and Sands—sands of various colours, with occasional beds of lignite; also layers of sandy clay, with or without shells.
1. Sands—green and ferruginous, accompanied by flint pebbles, oyster-shells, &c.

In other parts of England the order of occurrence is somewhat different. It may be stated, however, in general terms, that the sands are most extensively developed: the clays chiefly in the southern basins; while at Oxford, Ramsholt, &c., the upper beds consist of a coarse conglomerate of corals, sand, pebbles, shells, &c., locally known as the 'Crag,' and so calcareous in some places as to be used as a limestone. As with the Paris and English deposits, so with other tertiary basins in Europe; those of Southern France, Spain, Italy, Austria, Hungary, &c.—all shewing an irregular succession of clays, sands, marls, lignite (wood-coal), and gypsum, which, when examined in relation to their positions, modes of aggregation, and fossils, are clearly referrible to the same period of formation.

As developed in Europe, the tertiary system spreads over wide areas, all remarkable for their conformation and connection with the outline of existing seas. Indeed, were the islands and continent of Europe to be submerged to the depth of 600 or 800 feet, the waters of the German, Baltic, English Channel, and Mediterranean seas would cover most of the tertiary strata; shewing that, with the exception of the general elevation which raised them into dry land, there has been comparatively little subterranean disturbance since the time they were deposited.

Igneous rocks are not found in connection with the tertiaries of England, though subterranean movements have thrown them into anticlinal ridges and basin-shaped hollows. In the south of Europe the case is otherwise, and the geologist finds in the igneous discharges of Auvergne, Switzerland, the Rhine, Hungary, the Caspian, and Italy, a link which connects the traps of the secondary period with the products of recent and active volcanoes.

The organic remains of the system constitute its most important and interesting feature. The fossils of earlier periods presented little analogy, often no resemblance to existing plants and animals; here, however, the similitude is frequently so complete, that the naturalist can scarcely point out a distinction between them and living races.

From their relative position, and from the organic remains contained in them, geologists have been enabled to distinguish in the tertiary series of strata four great eras of deposit. To the oldest of the tertiary eras the term Eocene is applied; the second is called the Miocene period; the third, the Older Pliocene; and the fourth and latest, the Newer Pliocene—names founded on the respective proportions which their fossil shells bear to shells of existing species. In each of these periods is included a great fresh-water as well as a marine deposit. Of the animals which flourished in each

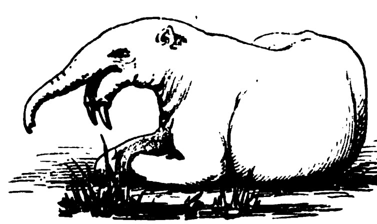
of these periods, we shall endeavour to give some account —premising in reference to the vegetable world, that the fresh-water beds have yielded cycadeæ, coniferæ, palms, willows, elms, and other families exhibiting the true dicotyledonous structure.

After the chalk formation, a period of considerable repose seems to have ensued, during which a large portion of the existing continents, and in especial the hollows and basins on their surface, appear to have been the site of vast lakes, rivers, and estuaries. From these was deposited the first great fresh-water formation of the Eocene period. While this deposit was going on, the globe was tenanted only by such quadrupeds as live beside rivers and lakes. Nearly fifty extinct species of mammalia, chiefly of this character, were discovered by Cuvier in the first Eocene fresh-water formation. The most of these belonged to the order Pachydermata (*thick-skinned* animals), of which the elephant, the rhinoceros, the hog, the tapir, and the horse, are remarkable existing examples. The extinct animals to which we now refer resemble the tapir more than any of the other Pachydermata. Among these extinct creatures, the most worthy of notice are the Palæotherium, the Anoplotherium, the Lophiodon, Anthracotherium, and one or two other families, including, some of them, not less than eleven or twelve distinct species. These mammiferous families had some general traits of resemblance, and the description of the great *Palæotherium* (ancient wild beast) may afford an idea of the main features of all. This animal was about four feet and a half in height to the wither, and somewhat squat and clumsy in its proportions. On each foot were three large toes, rounded, and unprovided with claws; the upper jaw was much longer than the under. The tapir, and partly also the hog, if large enough, would closely resemble the great palæotherium. 'The palæotheria,' says Buckland, 'probably lived and died upon the margins of the then existing lakes and rivers, and their dead carcasses may have been drifted to the bottom in seasons of flood.' The other mammiferous families of the first Eocene formation were all, like the palæotheria, herbivorous, and had, it is probable, similar habits.

Palæotherium.

The number of animals, aquatic and terrestrial, whose remains are found in the other deposits of the Eocene period, is immense. In some gypsum quarries of that era, scarcely a block can be opened which does not disclose some fragment of a fossil skeleton. The following list of the animals found in the gypsum quarries of Paris, will shew sufficiently how very different from the gigantic reptiles of the secondary eras were the creatures that tenanted, and found fitting sustenance on, the earth during the Eocene period. Besides various extinct pachydermatous families, there were extinct species of the wolf and fox, of the racoon and genette, among the carnivorous tribes; of the opossum; of the dormouse and squirrel; nine or ten species of birds, of the buzzard, owl, quail, wood-cock, sea-lark, curlew, and pelican families; fresh-water tortoises, crocodiles, and other creatures of the reptile class; and several species of fishes: all of these animals, be it remembered, being *extinct species* of existing families, exclusive of the pachydermatous animals and the fishes, which were extinct species of *extinct families*. The fossil shells found in the Eocene formations number many hundreds. As in the case of the terrestrial creatures, few of these shell-fish are of recent or existing species, not more, at the utmost, than three and a half in every hundred. We do not, moreover, recognise in the strata now under consideration those prodigious accumulations of *microscopic* shells, as they are called from their extreme minuteness, that distinguish the formations of the secondary or preceding ages. One small piece of rock, of the ages in question, has been found to contain above ten thousand chambered shells, though the whole weighed only an ounce and a half. In fact, great beds of secondary limestone seem to be almost wholly composed of microscopic shells. Such phenomena are not presented in the Eocene or subsequent tertiary deposits. The shells of these periods, as has been already observed, approximate more to the character of recent or existing species.

The second or Miocene period, however, of the tertiary ages, brings us a step nearer to the existing condition of things. Whereas only three in the hundred of Eocene fossils were of recent species, of the Miocene shells we find eighteen in the hundred to have existing representatives. Along with the mammalia, also, of the Eocene period, we find that the Miocene deposits present us with the earliest forms of animals existing at the present time. In Dr Buckland's Bridgewater Treatise, a table is given exhibiting the animals found at Darmstadt, in a bed of sand referrible to the Miocene period. In this list are mentioned two skeletons of the dinotherium, a large herbivorous animal; two large tapirs; calicotherium—two large tapir-like animals of this name; two rhinoceroses; hippotherium, an animal allied to the horse; three hogs; four large cats, some as large as a lion; the creature called the glutton; agnotherium, allied to the dog; and an animal allied to the bear. From this list the reader will perceive the gradual approach in the Miocene animals to existing species. The largest of the terrestrial mammalia yet discovered belongs to the period now under notice; it is the dinotherium, or gigantic tapir, already mentioned. No complete skeleton has yet been discovered; but from the bones found, Cuvier and others imagine the animal to have reached the extraordinary length of eighteen feet. The most remarkable peculiarities of its structure consist in two enormous tusks at the end of its lower jaw, and the shoulder-blade, which resembles that of a mole, and is calculated to have given the power of digging, or other free movement, to the forefoot. It is probable that this stupendous creature lived in fresh-water lakes, and had the half-terrestrial, half-aquatic habits of the walrus or river-horse.



Dinotherium.

In the Miocene period, the seas became the habitation of numbers of marine mammalia, consisting of dolphins, whales, seals, walrus, and the lamantin, or manati. Few of these animals were of the same species as those which exist at present; but the differences were far from being great or remarkable. This circumstance, as well as the considerable number of fossil shells identical with existing ones, exhibits an approach in the character and tenantry of the Miocene seas to the present state of things in these respects. The discovery, also, of true terrestrial mammalia, as the rhinoceros and hog, in the Miocene formations, shews that since the era of the gigantic reptiles a large portion of the earth's surface had assumed the condition of dry land, fit for the support of the common herbivorous creatures. At the same time, the occurrence of such animals as the dinotherium proves, as

Dr Buckland remarks, that many regions were still covered with great lakes and estuaries. It now remains to inquire into the nature and peculiarities of the animals characterising the Pliocene age, which, for convenience, has been arranged into two periods, the Older and Newer Pliocene: whereas only eighteen in the hundred of the Miocene shells were of recent species; in the Older Pliocene, from thirty-five to fifty, and in the Newer Pliocene, not less than from ninety to ninety-five in the hundred, are identical with shells of existing species. This great change is accompanied by the disappearance of the Palæotherian family and others, which formed the most striking animal remains of the periods immediately preceding. In place of these extinct species of *extinct* Pachydermatous or thick-skinned families, we observe in the strata of the Pliocene periods a vast number of remains of *existing* Pachydermatous families, such as the elephant, the rhinoceros, and the hippopotamus, though these remains belong to varieties that are now extinct. The first traces also now appear of ruminant animals—of oxen, deer, antelopes, camels, and other creatures of the same class. But though it is of importance to notice the existence of such remains in the Pliocene ages, in order to exhibit the progressive approach to the current state of things in the animal kingdom, it is in the huge and extraordinary creatures, now no longer to be seen on the face of the earth, that the interest of such an investigation as the present chiefly lies.

The enormous creature called the *Great Mastodon* belongs to the Pliocene era. Of all the fossil animals whose skeletons have been found *complete*, or nearly so, the mastodon is the largest. It is about 120 years since its remains were first discovered in America, and vast quantities of them have been since found in the same region, buried chiefly in marshy grounds. One skeleton, nearly complete, was dug up on the banks of the Hudson in 1801, and it is from this that a correct knowledge of the animal has been principally derived. In height the mastodon seems to have been about twelve feet, a stature which the Indian elephant occasionally attains. But the body of the mastodon was greatly elongated in comparison with the elephant's, and its limbs were thicker. The whole arrangement of the bony structure resembled that of the elephant, excepting in one point, which Cuvier regarded as of sufficient consequence to constitute the mastodon a different genus:—this was the cheek-teeth, which are divided on their upper surface into a number of rounded obtuse prominences, arranged not like the elephant's, but like those of the wild-boar and hippopotamus; whence it is concluded that, like the latter animals, the mastodon must have lived on tender vegetables, roots, and aquatic plants, and could not have been carnivorous. The lower jaw of the skeleton found on the Hudson is two feet ten inches in length, and weighs *sixty-three pounds!* Like the elephant, the mastodon had two tusks, curving upwards, and formed of ivory; and in the opinion of Cuvier, it had also a trunk of the same kind with the former animal's. Altogether, making an allowance for several additional feet of length, it may be considered as varying but little from the larger specimens of the elephant. From the immense number of mastodon bones which have been dug up in various parts of the earth, and particularly in the New World, we must conclude that at no distant period of time the terrestrial surface was extensively peopled by these enormous creatures.

Another creature, belonging to the later Pliocene ages, if not indeed to the era of the diluvial formation, has been discovered in America, both north and south. This is the *Megatherium* (great wild beast), an animal more widely removed in character from any existing creature than any of the other fossil remains that have been yet observed. The megatherium was discovered towards the end of the last century. A skeleton, almost entire, was found nearly at one hundred feet of depth, in excavations made on the banks of the river Luxan, several leagues to the south-west of Buenos Ayres. The megatherium was a tardigrade (slow-moving) animal, like the sloth, but of gigantic dimensions, and calculated to subsist on roots and succulents, and on the foliage and young shoots of trees, for the pulling down and uprooting of which its structure seems to have been admirably adapted.

Associated in the same set of deposits—that is, in detrital beds of somewhat later origin than the tertiaries of Europe—Mr Darwin has discovered in South America the remains of several gigantic quadrupeds besides those of the megatherium. Of these the most remarkable are —the *Megalonyx*, nearly allied to the megatherium; the *Scelidotherium*, an animal as large as the rhinoceros, but partaking of the character of the Cape ant-eaters and armadilloes; another great armadillo-like animal with a bony covering; the *Macrauchenia*, a huge beast, with a long neck like a camel; and the Toxodon, perhaps the strangest animal ever discovered. The macrauchenia is described as belonging to the same division of the pachydermata as the rhinoceros and tapir, but shewing in the structure of its long neck a clear relation to the camel, or rather to the alpaca and llama. As to the toxodon, it equalled in size the elephant or megatherium; but the structure of its teeth proves indisputably that it was intimately related to the gnawers, the order which, at the present day, includes most of the smallest quadrupeds. In many details it is allied to the thick-skinned animals; and, judging from the position of its eyes, ears, and nostrils, it was probably aquatic, like the dugong and manatee, to which it is also allied. 'How wonderfully,' remarks the discoverer, 'are the different orders, at the present time so well separated, blended together in different parts of the structure of the toxodon!'

SUPERFICIAL ACCUMULATIONS.

When the geologist has described the series of formations terminating with the highest Pliocene, it remains to him to account for the general mould of the surface, and take some notice of the accumulations of loose matter lying upon it. It is very readily manifest to him, that, since the deposition of the last genuine rock stratum and the occurrence of the last considerable volcanic disturbances, inequalities have been reduced and smoothed off, excavations have been made, and much clay, sand, and other matters has been deposited. Water and ice are called into view as agents in the production of these phenomena.

The reducing and smoothing process has been conducted on a scale far beyond what any one could have been prepared for. In districts of the primary rocks, we find the upper parts of great folds cut away, to the depth of many hundreds of feet. In the secondary rocks, where dislocations to an equal extent have taken place, instead of finding the one side rising to that height above the other, all is smooth. In many places vast cuttings have been made, which no running streams can account for. These *denudations*, as they are called, are generally thought to be the result of marine action; but it is probable that the views of geologists on this subject will yet undergo a great modification, as water does not in general leave smooth surfaces, or make great scoopings, without leaving equally great ruins behind it.

In intimate connection with the moulding process is the nature of the superficial accumulations. It is necessary to inquire what these are.

In the northern regions of both Europe and America, wherever any considerable mass of the superficial accumulations exists, it presents a variety of materials alternating in something like a uniform order. In some situations, and particularly in Scotland, there are not fewer than six beds of these various materials; it is seldom there are fewer than three. The deposit most generally found in immediate contact with the surface of the rock, is a hard compact paste of blue or ruddy clay, mixed confusedly with worn fragments of rock. In

Scotland, this is known as the Boulder Clay, or Compact Blue Clay. It is in very many places ten or twelve feet in thickness—in some as much as a hundred, or even more—but in some it is only two or three feet thick. When it is removed, we generally find the surface smoothed and scratched, as the beds of glaciers are seen to be at the present day. Its constitution indicates its being formed in circumstances of violence and confusion; but these must have been occasionally interrupted, for here and there occur in it thin beds of tranquilly deposited sand and gravel.

Resting on the boulder clay in some places is a deposit of fine silt clay, apparently the washings of the subjacent hard deposit, and well known for its serviceableness in making bricks, tiles, and earthenware. Beds of this clay alternate with beds of fine sand, and amongst them it is common in Scotland to find arctic shells, with bones of large ruminant animals and pachyderms.

Next occurs a coarse gravel, compacted with clay or with metallic oxides; altogether much resembling the rough matters left on the brink of Alpine glaciers. Over this, again, in Scotland, are further beds of fine sand and clay alternating, till we come to the vegetable soil, which is merely a mixture of the surface matter with the remains of decayed plants and animals.

The prevalent opinion regarding the boulder clay is, that it has been formed in an arctic sea charged with icebergs and packs of ice, which have passed grazingly over and worn the sea-bottoms, carrying along and finally depositing the detritus as we see it. It may be safely predicted, however, that this theory will not stand, as it is far from adequate to account for the obvious connection of the productive agent with the agency which has produced the entire mould of the country in its varieties of hill and dale. Drifting ice, it may be admitted, will graze coasts and sea-bottoms here and there, and deposit considerable quantities of detritus; but it could never work with equal force over an unequal sea-bottom, leaving large and small eminences, throughout the entire area involved, in precise proportion to the comparative hardness of the parts, as we find to be actually the case. The uniformity of the direction of the striation of the subjacent rocks over large areas—areas often most unequally moulded—is also irreconcilable with the idea of simply floating or drifting ice. The exigencies of the case demand a more hard-pressing application of the agent; an application, too, which at once affected the lowest parts of the surface, forming therein often the finest groovings and channelings, and moulded the swellings of hills of at least a secondary magnitude.

The sand-beds intercalated in the boulder clay, and the alternating beds of fine clay and sand lying above it, containing arctic shells and remains of deer, elephants, &c., indicate a period of tranquil conditions, during which this country was partially covered with an arctic sea, bordered by lands such as Siberia and Norway now are.

The coarse gravel, resembling as it does the spoils of modern glaciers, strongly suggests a time of elevation of the land, during which high valleys were filled with moving ice, the masses of which, descending to the sea and there breaking off, carried out great quantities of rough matter, which, as the process of melting went on, they distributed over the sea-bottom.

A subsequent sinking of the land may be presumed to have caused a recommencement of the process of the formation of alternating sands and gravels. There is great reason to believe that many of the larger masses of the latter material are the washed remains of the deposits formed by glaciers; but this we have no room on the present occasion to demonstrate. The superficial powdering of erratic blocks which is so remarkable in all northern regions, may very reasonably be ascribed to the transporting power of floating icebergs.

It thus appears, from the superficial accumulations, that there was a long period during which great tracts of northern land were submerged, raised, and probably submerged again. There had also been at that time a lower average temperature than at present. The general tendency of the study of this superficial formation is to shew that it represents a vast stretch of time and a considerable variety of conditions. It is tolerably certain that no great change of the relative level of sea and land has taken place in the historical era of two or three thousand years. During the time the present relative level has been maintained, however much longer than the space of the historical era, a certain cut has been made in the fabric of the land, forming the present beach. But in the west coast of Scotland, twenty-five feet above the present beach, is an ancient one much more deeply indented, and we find lying upon this elevated beach the spoils of valley glaciers, bearing evidence of subsequent marine action. Here, then, is the memorial of only one in the series of conditions exhibited by the superficial accumulations; and we clearly see that it represents a period of many thousands of years.

The latest series of geologic changes has been the rise of the land out of that deep immersion in the sea which the superficial formation evidences. We have clear proof that this emergence was not sudden and complete, but slow, and by a series of movements. This proof lies in the existence of *ancient beaches* at various elevations above the present shore. We generally detect such an object by its levelness along some considerable tract, and by the indentation of rocks, or the deposit of sands and gravels, mingled as these occasionally are with deposits of shells. All our valleys exhibit such terraces more or less conspicuously, proving that they were at one time the beds of estuaries.

Of man himself no remains have been found, save in the most recent and superficial deposits—as alluvial mud, calcareous breccia, volcanic tufa, and the like—thus proving him to be one of the latest, if not the very latest, inhabitant of this globe.

SUMMARY.

The history of the earth thus presents a long series of mineral and vital gradations, as yet but imperfectly interpreted by geology. The stratified formations, from the gneiss to the existing surface, bear evidence of these gradations, both in their composition and modes of aggregation; so also do the unstratified rocks—the granitic, trappean, and volcanic compounds—by the order in which they succeed each other. We see in these successive formations the fragments, as it were, of a history of organic being. We look in upon it, it may be said, from time to time, find that many changes have taken place in the intervals, yet always see a connection between the present and past, assuring us that the whole is essentially connected. We see, too, that a steady progress has been maintained all through, from invertebrate to vertebrate forms, from the fish to the reptile, and from the reptile to the warm-blooded animal; man finally coming upon the scene as a crowning work. It is a most interesting and elevating study, never failing, we believe, in well-ordered minds, to exalt our conception of the Divine power and excellence.

METEOROLOGY.

METEOROLOGY explains the laws which regulate weather, seasons, and climates. It involves particularly the consideration of the atmosphere—its magnitude and height above the surface of the earth; its weight or pressure and elasticity, and the gradations of these as we ascend; the materials and manner of its composition; the alterations made upon it by heat and cold; and its electrical condition. It is by an accurate knowledge of these that we are enabled to understand the nature and causes of the incessant movements and changes going on in the air around us, and of the ever-varying appearances of the sky over our head; including the phenomena of winds and storms, of rain, dew, hail, snow, mists, and clouds, and their connections with one another, and with seasons and places.

THE ATMOSPHERE.

Its Composition—General Structure—Density—Pressure.

The atmosphere is a vast ocean of invisible gaseous matter, enveloping the terraqueous globe, and extending to a considerable height. Although it cannot be seen by the eye, it is yet felt to be an inert, material mass, which resists bodies in their motion through it, and when set in motion itself, possesses momentum or impetus, like a flying ball or a running stream. Another property of the atmosphere, which proves its genuine materiality, is its weight or pressure. It presses upon the earth, exactly as the sea does, under the influence of gravitation. This pressure is in proportion to its quantity, and its natural or specific gravity. When we ascend to a great height above the ordinary level of the ground, as to a mountain-top, the pressure is diminished, because the quantity lying above becomes less. At the sea-level, the average pressure is 14¾ pounds on every square inch; it is nearly the same as the pressure of a lake of water 33 feet deep, or a lake of mercury 2½ feet deep. The construction of the barometer, or instrument for constantly measuring this weight, and shewing the degrees of its fluctuation from day to day, is explained under PNEUMATICS. By it the air is made to sustain a column of mercury, which is higher or lower according as the whole weight of the atmosphere above increases or diminishes; and therefore, by looking at the height of the mercury, we know at any instant the weight of the atmosphere at that spot.

The average height of the mercurial column is somewhat less than 30 inches at the level of the sea; but it fluctuates to such an extent, that it sometimes descends to 28 inches, and sometimes rises to 31. A low barometer proves that some cause or other has carried away a mass of air from that particular locality; and a high barometer proves that the opposite action has taken place.

The atmosphere is therefore to be considered as a mass of gaseous or aërial fluid enveloping the earth, and pressing on its surface with a weight amounting to 14¾ pounds (14·7) on every square inch. This fluid is found to be not a single substance, but a mixture of several substances, totally distinct in their properties, and serving quite different offices in the economy of nature. The two chief ingredients—nitrogen and oxygen—which make up more than $\frac{49}{50}$ths of the whole mass, are as different in their character as water and alcohol. The proportions of these two are very nearly 77 of nitrogen to 23 of oxygen by weight; that is, 100 pounds of air contain 77 pounds of nitrogen, and 23 pounds of oxygen. The nitrogen is therefore the principal element in point of quantity; but the oxygen performs the greatest variety of functions: it is the supporter of life, and the indispensable agent in combustion, in putrefaction, and in many other natural processes.

Deferring in the meantime the consideration of the other ingredients of the atmosphere, we have to study in the first place the mode of mixture of these two gases, and the general structure of the mass they compose. Although the mechanism and constitution of a gas are not apparent to our senses, yet we can infer with certainty that it is made up of atoms which keep one another at a distance by a repulsive force. From the fact that any gas can be compressed into a very small fraction of its ordinary bulk, we are sure that its particles are usually at a great distance from each other in comparison with their size. If we imagined a flight of crows, each fifty feet every way apart from the next, we should have some idea of the spread of gaseous atoms in empty space.

If we take, then, any single gas, such as nitrogen, we may be certain that its particles stand asunder from each other at very great distances compared with their size; and these distances are all equal, for the nature of the repulsion is such, that there is no rest nor stable balance if a particle is nearer its neighbour on one side than on the other. But when two gases are mixed, the circumstances are changed. We are still sure that each will repel its own kind, but we cannot say beforehand whether or not the particles of one kind will repel the particles of another kind. Experiment seems to warrant the conclusion that they do not; and therefore, when oxygen and nitrogen are mixed, it is as if we introduced among the crows, already supposed scattered at a rigid distance of fifty feet, a flock of pigeons, held apart a hundred feet from one another, but not under any repulsion from the crows; so that while the distances of each kind among themselves are equal and fixed, there would be the greatest variety of distances between pigeons and crows, from close contact to a hundred feet. Considering also the immense amount of empty spaces between the crows, the admission of the pigeons would be almost as free as if the space was altogether empty: each kind might move and expand almost as if the other did not exist.

Oxygen probably does not repel nitrogen. It is not so certain from the facts, whether oxygen and nitrogen are perfectly indifferent, or whether they have a slight attraction. There are many analogies which render it likely that strange gases may in some cases attract each other.

Taking the entire mass of the atmosphere, considered as an ocean of gaseous or elastic fluid, its density must diminish as we ascend from the earth. The tendency of air being to expand to the utmost limits allowed, it would fly off into the boundless regions of space if it were not kept on the earth by the force of gravity or by its weight. The portions at the earth's surface not only lie upon it by their own weight, but they are compressed by the weight of all that lie above them; and in consequence they are compacted into a smaller bulk than they would otherwise have. The bulk occupied by any amount of gas diminishes exactly in proportion to the weight laid upon it. Thus, if a cubic foot of air at the earth's surface—which owes its actual density to a compression of 14¾ pounds to the square inch, arising from the weight of the whole height of air lying over it—were pressed with a weight of 29½ pounds to the square inch, its bulk would be reduced to half a cubic foot; or if half the usual

weight were taken off, and the pressure reduced to 7½ pounds to the square inch, it would expand to the bulk of two cubic feet; and so on. Hence, if we ascend so high that one-half of the mass of the air would be below us, and the other half above us, the compression would be only 7½ pounds to the inch, and the air would be twice as rare as at the earth, or it would have only half the density. Two cubic feet of such air would be equal in weight to one cubic foot of air taken at the earth's surface.

The density of the air therefore diminishes upward in the exact proportion of the diminished weight of the mass. It can be determined by calculation at what heights the weight and density will be of any given amount. Thus, at 20,000 feet above the sea, the density is less than half that at the earth's surface; on the highest summits of the Andes or Himalaya, it is about one-third, or three cubic feet of air weigh no more than one cubic foot at the sea-level.

There is another cause besides the decrease of weight to affect the decrease of density—namely, the increased capacity of the rarefied air for heat. If a cubic foot of air is allowed to expand to two cubic feet, it requires to absorb additional heat into its mass in order to keep up its temperature. It is said to have acquired a greater capacity for heat; and if it do not receive an extra quantity, it will cool down, or it will have a much lower temperature than in its former state. So that the air at 10,000 feet of height will, by its expansion, require more heat to keep up the temperature; and as it has no means of getting more than the surface-air, but, in fact, receives rather less, it will be very much colder than the air below. The first consequence of this cooling is a loss of elasticity, which causes it to contract under the pressure to which it is subject, and to occupy a smaller space than it would have occupied if the temperature had been kept up by a new supply of heat. Thus a cubic foot of air, when half its pressure is taken off, becomes two cubic feet, only on the supposition of receiving so much heat as to make the two feet as warm as the one foot; failing this, it cools down, and contracts to somewhat less than two cubic feet; so that when this new cause is taken into account, the density of the air does not diminish quite so fast as the weight diminishes. The whole atmosphere is more compressed or more dense than if the law of diminished weight and density were to hold strictly; we do not require to ascend so far to pass through a certain amount of it—that is to say, we shall reach the point of 7½ pounds pressure at a lower level.

When allowance is made for the effect of the increased capacity of the air for heat, with the cold and contraction thence arising, the weights and densities of the air at different heights are as in the following table, which exhibits in the fourth column the decrease of temperature at each height, beginning at 32°:—

Height in Feet.	Barometer Column in Inches.	Density.	Temperature.
0	30·000	1·00000	32°
5,000	23·949	·82656	14·8
10,000	19·106	·68321	— 3·1
15,000	15·229	·56472	—22·4
20,000	12·044	·46677	—43·6
25,000	9·579	·38582	—67·5
30,000	7·566	·31890	—95·1

In this way the atmosphere goes on, becoming rarer and lighter, and at the same time colder, as we ascend, until it ceases altogether. At what height it actually terminates, we do not at present know; it can be with certainty affirmed to extend to fifty miles from the earth, as at this height it exercises a sensible effect in refracting light; but for anything that is known, it may extend to eighty or ninety miles. Its own elasticity would carry it away without limit, if something did not counterbalance the expansive force. But the weight of the particles, or their gravity towards the earth, serves as a counterbalance on the one hand, and on the other hand, the cooling caused by extreme rarity diminishes the force of the elastic spring; so that where the diminished elasticity is no more than a balance for the weight, there the atmosphere will terminate. For a few miles below this termination, it must be extremely rare, or little else than a vacuum. For all practical purposes, therefore, the height or depth of the atmospheric ocean is at present assumed as about fifty or sixty miles; but the great body of it is accumulated near the earth's surface. In reality, one-half of its material mass lies within three miles from the earth, and three-fourths of it within less than six miles. Its pressure on the highest pinnacles of the earth's surface is less than one-third of the whole weight as experienced at the sea-level.

MOVEMENTS OF THE ATMOSPHERE.

All the movements and changes to which the air is subject, originate, some way or other, in the application of heat. So long as an equal temperature is kept up, the air continues at rest; but the slightest addition or subtraction of heat in any part of it leads to a series of movements that may extend to a great distance all around. The nature of these movements requires to be distinctly explained.

If the temperature of the whole surface of the earth, being at first supposed everywhere the same, were to rise equally at once, the effect would be to expand and elevate the atmospheric ocean without producing any other movement. The upper surface would stand higher, and the equal divisions of the mass would also be higher. There would be no side-motions or horizontal currents created; each column would be lengthened, but its particles would remain over the same spot as before. But if we now suppose that the surface of the earth is unequally heated, as in fact it is, a new action will ensue. If two adjoining spots of ground are of unequal temperature, and communicate an unequal temperature to the columns of air lying upon them, the column which is most heated will be expanded in its whole length, so as to overtop the other, and it will be made rarer or lighter all through. Two effects will arise from this: a lateral or horizontal movement of the air from the cold to the warm column will take place *below*, according to the general law of hydrostatics that a heavy fluid buoys up a light one. But if we consider the condition of the two columns *above*, or at their upper ends, we will find that the opposite effect must arise; that is, a movement will take place from the warm column to the cold; for the warm column being to some extent lengthened or elevated, a considerable mass of it will be thrown further up than an equal mass of the cold column. Not only will the uppermost portion of the long column, which rises to a point where the short column has ended, and has therefore nothing but a vacuum to flow to, have a side-movement towards the other, but portions far beneath the top will have a pressure so much greater than the contiguous portions of the shorter column, that they too will flow out laterally, and determine a current tending to equalise the difference of heights and pressures.

When a difference of temperature exists between two spots that lie near one another, the effect of the aërial currents which take place between them is to equalise the temperature; the cold air is brought into contact with the hot ground, and the hot air with the cold ground, and gradually the heat of the one is reduced, and that of the other raised, till both become exactly the same. The air lying over them will then be the same, and all movement will cease. Thus the lateral currents arising from differences of terrestrial heat tend gradually to abolish those differences, and bring all to one uniform pitch. The air is the carrier of warmth from over-heated to under-heated localities, and moderates both extremes. Its lateral currents are the effect of unequal

heating, and in some measure the remedy. These lateral currents are felt and recognised by us under the name of *winds*. If the differences of warmth that originate them were only limited and temporary, the carrying of heat to and fro would bring about an equality, and then the air would come to a perfect repose; but these differences of warmth are perpetually kept up, and, notwithstanding all the influence of the under and upper winds, they exist to a very large amount; hence the lateral currents go on for ever without ceasing. The middle band of the earth, or the equatorial zone, is exposed to the burning radiance of a direct sun, while the two polar regions are so faintly heated, that snow never melts upon them; and this great standing inequality keeps up two grand sets of movements, which encompass the globe. The equatorial air, being warmer and lighter below than the air on each side, is buoyed up by the cold masses moving in upon it from north and south, and thus two great under-currents are maintained between the poles and the equator. The equatorial mass being expanded far upwards, overtops and overpresses the upper portions of the colder columns on each side, and therefore flows in upon them on both sides, making one movement towards the north pole, and another movement to the south pole; thus causing two great upper-currents towards the poles, while the under-currents are moving from the poles. The inequality of the equatorial and polar regions in respect of heat is thus in some degree mitigated; but it is by far too great to be entirely done away. If there were no such currents, the equator would be hotter, and the poles colder than now; but even as it is, the difference is enormous, and causes the two vast and incessant movements which we have now endeavoured to describe.

We have supposed, for simplicity's sake, that the atmosphere is divided into an equatorial and two polar masses; but in reality there is a constant gradation from the equator to the polar regions, and the movements will take place between every two adjoining portions of atmosphere of which one is further north or south than the other.

Although, as a general rule, the temperature of the earth decreases from the equator to the poles, this is not strictly or at all times true. Various causes occur to render a high latitude as warm as, or warmer than a lower, and in such a case a contradiction will arise to the general movement, which will have peculiar local consequences.

If we take the case of the heating of the air, not at the surface of the earth, or the base of an atmospheric column, but at some high elevation, a new train of consequences will ensue. Let a portion of air, from 10,000 feet upwards, receive an accession of heat, while the temperature of the portion below remains the same—the first effect will be an expansion and rising of the whole length of the column above 10,000 feet; the upper regions will have thus an increased pressure, and overflow all around. If the equatorial current is passing along these regions, it will be met and resisted by this local current, and on one side the equatorial air will accumulate unduly, and on the other side there will be a deficiency. There is here a movement created above, *without a counter-movement below*, and consequently air will be flowing away from the heated column, and no new air flowing in; hence its quantity or pressure will diminish, and the barometer, which measures the pressure, will fall.

VAPOUR OF THE ATMOSPHERE.

Vaporisation—Dew—Mist—Clouds—Rain—Hail—Snow.

Next in quantity to nitrogen and oxygen, although very small compared with these, is the vapour of the atmosphere; that is to say, the gaseous water or steam that is constantly present in it. Although very trifling in amount, this portion of the atmosphere is of immense importance in its effects. Unlike the other gases, it is easily reduced from the aërial to the liquid form, or to water as we usually find it; and it is constantly going through the processes of becoming liquid, and descending to the earth, and again rising into the air in the gaseous or invisible form. The great agency connected with these transformations is heat. When water passes into steam, it takes in a large amount of heat, which is rendered insensible to the feeling or to the thermometer; and when steam or invisible vapour is condensed into water, all this heat is given out again.

It is essential to bear in mind that true gaseous water, steam, or elastic vapour of water, which all mean the same thing, is invisible, like the other portions of the atmosphere; and that the white cloud that appears at the chimneys of steam-boats and locomotives, and at the spout of a kettle, is not gas or elastic vapour, but vapour partially condensed, whose particles only require to be brought together to become drops of water. It is, in fact, water in the form of something like dust. Mist, fogs, and clouds are of the same character: they are not gaseous steam, but precipitated watery particles destitute both of mutual repulsion and of the latent heat of steam. All visible vapour, therefore, is an intermediate state between elastic invisible vapour and water. If the atmosphere contained nothing but true steam, it would be transparent and cloudless.

The formation of steam out of water is most conspicuous in the process of boiling, where the surface is kept in an intense bubbling state, each bubble containing a mass of steam, which forces its way up into the air. This boiling takes place at 212° of the thermometer, called for that reason *the boiling-point*. The steam thus formed has an elastic force equal to the pressure of the atmosphere, or a force of 14$\frac{3}{5}$ pounds to the square inch; that is, when admitted into the cylinder of a steam-engine, below the piston, it forces the piston upwards with a power that it would take 14$\frac{3}{5}$ pounds on the square inch to balance; or a piston of ten square inches would be buoyed up as with a weight of 146 pounds. The reason for the *violent* escape of steam at 212° is, that it has attained a force equal to the weight of the atmosphere pressing on the water, and is therefore able to set aside this pressure, or make its way in spite of it. But even at temperatures below boiling, water passes into steam slowly and invisibly. It is well known that a wet surface soon becomes dry; in other words, that the water upon it disappears. Water, however, cannot be annihilated, or pass out of existence—it is impossible to annihilate any substance that has weight—in the drying process, the liquid water becomes gaseous invisible water or steam, and mixes with the other steam contained in the air. But for this disposition of water to pass into the aërial state, it would remain as permanent on a spot as paint or plaster.

The rapidity of the process of drying up, or of the passing of water into steam, depends, in the first place, on the temperature of the water. We have seen that it is abundant and violent at 212°; and it is less and less for every degree downwards. The elastic force of the steam produced also depends upon the temperature. The elastic force of steam at the boiling-point is equal to the pressure of the atmosphere; while the elastic force of steam produced silently at 80° is only $\frac{1}{30}$th of the elasticity of the atmosphere, or equal to one inch of the barometer.

Now, the entire quantity of steam that can rise is limited by the temperature in the same manner as the elasticity is limited. Water at 80° will give forth vapour, until as much has been produced in the atmosphere as would counterbalance one inch of mercury; evaporation then ceases, and the air is said to be *saturated* with steam. Whether the steam rise freely into the atmosphere, or rise into a vacuum, no more will be produced at 80° than this quantity. If the temperature were raised to 90°, there would be the means of supporting an additional quantity of steam, and evaporation

would again go on, until as much were distributed through the air as of itself would counterbalance 1·36 inches of mercury, or about $\frac{1}{22}$d of the weight of the whole atmosphere. With every new addition of heat, new evaporation would go on, which would be of the silent kind up to 212°, when the full pressure of the atmosphere would be reached. If an extensive lake were at this extreme temperature, steam would be produced from it, until as much were diffused through the air as would press upon the ground at the rate of 14¾ pounds to the square inch, or sustain 30 inches of mercury; the other air of the atmosphere and the steam together would raise the barometer to about 60 inches, which is called a pressure of two atmospheres. But as the water on the earth's surface does not rise much above 80° even at the equator, and is far below this temperature in other regions, the whole weight of vapour in the air rarely amounts to one inch of mercury; so that if the pressure due to nitrogen and oxygen by themselves were 29½ inches, the whole pressure, including the vapour, would be only about 30 inches, and at the utmost 30½ inches.

It has been stated, that at 80° vapour rises till as much exists in the air as weighs an inch of mercury; and that if the heat be increased, an additional quantity can be produced and supported. Let us now consider what must happen if the air were saturated with all that could be maintained at 80°, and if the temperature were then lowered, say to 60°. While at 80°, the vapour may amount to an inch; at 60°, it amounts only to ·52, or little more than half an inch. If, therefore, the full quantity which can subsist at the higher temperature has been produced, and if the temperature then descend to the lower point, there will be nearly half an inch too much for the reduced temperature, and this excess will be thrown out in the state of visible non-elastic vapour, or fall down as liquid drops. There will be either some kind of fog, cloud, or mist, or the aggregation of these into watery coherence.

TABLE, shewing the Elasticity of the Vapour that can be maintained at each Degree of Fahrenheit, from 0° to 90°, expressed in Inches of Barometric Pressure.

When as much steam exists as can be maintained at the temperature which the earth and air have at the time, *saturation* is said to take place. Thus, at the temperature of 70°, ·727 of an inch would suffice for saturation; and at 32°, ·199, or about one-fifth of an inch, would have this effect. But if less steam is formed than could be supported at the temperature, there is said to be a certain amount of *dryness* or *thirstiness* in the air; meaning that there is room for further evaporation. Thus, if at the temperature of 65° there exists only half an inch of invisible vapour, the air is below saturation, and gives an opening for more to rise out of the water lying on the surface of the earth. The air is dry to the extent of one-tenth of an inch of the barometer; for at 65°, about six-tenths of an inch could be supported, while only five-tenths exist; evaporation may therefore go on till the additional tenth is supplied, and then the air will be fully saturated.

The degree of dryness or thirstiness can be measured by the difference between the amount of vapour existing, and the amount that might exist under the temperature. Thus, if the temperature were 40°, and the vapour a quarter of an inch, the dryness would be the difference between ·25 and ·264—which is the amount sustained at 40°—or ·014; that is, $\frac{14}{1000}$ths of an inch of the barometer. So if the temperature were 85°, and the vapour nine-tenths of an inch, the dryness would be ·9 subtracted from 1·171, or ·271, which is a little more than one-fourth of an inch. It is on the amount of this difference that the rapidity of evaporation depends, or the quickness of the process of the drying up of wet surfaces. In the case last mentioned, where the dryness is ·271, the rapidity of evaporation would be about twenty times as great as in the previous case, where the difference was ·014.

If the quantity of vapour in the air is less than what is supportable at the temperature for the time being, there is some lower temperature which this quantity would completely saturate. Such temperature is called the temperature of the *dew-point*. Thus, if there were three-quarters of an inch of vapour existing, the temperature that this would saturate will be found from the table to be 70°—the number at 70° being ·727, or very nearly three-fourths; 70° is therefore the temperature of the dew-point for this amount. It is so called because the smallest cooling below 70° would bring out visible mist, and cause dew to be formed on adjoining surfaces. The dew-point is the lowest point to which the air can be cooled down without giving out visible moisture. If the air were saturated, the temperature and the dew-point would be the same; if the air is dry, or not saturated, the dew-point temperature is below the air temperature; and the difference between the dew-point and the temperature of the air is a measure of the dryness.

The number of degrees of Fahrenheit between the air temperature and the dew-point temperature is not, however, the exact estimate of the dryness, as will be seen from the following example. Suppose the temperature of the air 80°, and the dew-point 70°, then the amount of additional vapour that could be supported would be found thus:—

Vapour sustainable at 80°, 1·001 inches.
" " 70°, ·727 inch.
Difference, . . ·274, above a quarter of an inch.

Thus a difference of 10° of temperature makes a vacancy for a fourth of an inch of vapour. Take now a difference of 10° further down in the scale. Suppose the air 40°, and the dew-point 30°:—

Vapour sustainable at 40°, ·264 inch.
" " 30°, ·186 "
Difference, . . ·078, about 1-12th of an inch.

So that a difference of 10° between 70° and 80° makes a dryness or deficiency three times as great as a difference of 10° between 30° and 40°. Water would disappear three times as fast in the one case as in the other. Hence to know accurately the dryness of the air at any time, we must reduce the difference of temperatures to barometric inches, according to the preceding table.

If vapour existed in empty space, with no other gas along with it, the quantity existing at any one time would be determined by the barometer. But as, in fact, the vapour is only a very trifling portion of the mass of gases which press upon the earth, the barometer cannot give its value separately; the mercurial column expresses

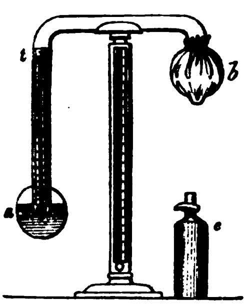
only the pressure of the sum-total of the atmosphere. Hence some other means must be adopted for finding the amount of vapour by itself. Instruments used for this end are called *hygrometers;* from the Greek *hygros*, moist, and *metron*, a measure.

Apart from instruments, we judge of the dryness of the air, or of the additional amount of vapour which it could sustain, by the time required to dry wet bodies, such as the ground, or wet clothes hung in the air. We call that a dry day which makes water disappear rapidly from all surfaces, and which keeps the air clear and transparent. On the other hand, when wet clothes are found to make no progress towards drying, we call the day damp or moist; the air in this case being saturated with vapour.

The chief instruments for determining with perfect accuracy the dryness of the air, and the actual amount of aqueous vapour that it contains—technically its *hygrometric condition*—are Daniell's hygrometer, and the wet and dry bulb thermometers.

The principle of Daniell's hygrometer is to cool the air down upon some surface till dew appear, and to mark the temperature when this happens. Thus, suppose a tumbler standing in the open air is cooled by pouring in cold water, or any other cold liquid, until the sides of the tumbler are covered with dew, the temperature of the glass at the moment that the dewing begins will be the temperature of the dew-point.

The construction of the hygrometer is as follows:—A central pillar or stalk has a thermometer attached to it, and carries across the top a glass tube, bent down at each end, and terminating in two bulbs *a* and *b;* the longest branch has a thermometer *t*, inside whose ball is the centre of the bulb *a*. The tube and bulbs are perfectly air-tight, and contain a quantity of ether, which is seen partially filling the lowest bulb. The bulb *b* is covered with muslin, and the bulb *a* is either blackened or covered with a metallic coating. The inside of the tube contains, besides the liquid ether represented around the thermometer-ball, an atmosphere of gaseous ether, which is expanded through its whole interior, and into the muslin-covered bulb *b*. Along with the instrument, there is used a small bottle of ether *e*, with a bent tube in its mouth, to allow the liquid to be poured out in drops. The instrument is placed exactly as in the figure when an observation is to be made; and the two thermometers are supposed to be both at the temperature of the air. The observer then takes up the little bottle, and drops ether on the muslin bulb. The ether being exceedingly volatile, evaporates rapidly, and cools the bulb; and this cooling has an effect on the gaseous ether within, and condenses a portion of it; which condensation leads to a fresh evaporation from the liquid ether in the lower bulb, and consequently to the production of cold within that bulb, and the cold goes on increasing in it so long as ether is dropped on the muslin. The temperature of the thermometer-bulb is thus steadily falling, and in the course of a short time it will descend to the dew-point temperature, and the outside of the bulb will become visibly dewed. The instant of the dew's appearing is what the observer has to note, and also the height of the enclosed thermometer at this instant, for the temperature of deposition is strictly the dew-point temperature. To make the observation more accurate, the bulb is allowed to become warm again, by ceasing to drop ether on the other bulb, and notice is taken of the moment that the dew disappears, and of



the enclosed thermometer at the instant; the mean of the two temperatures—the temperature of deposition and that of clearing—will accurately express the dew-point. The thermometer on the central pillar gives the air temperature at the time of the observation, and enables the observer to ascertain the dryness of the air by determining the difference of the two.

The determination of the dew-point by the wet and dry bulb-thermometers depends on the effect of evaporation in causing cold. When water passes into invisible vapour or steam, it absorbs from whatever substances it touches a large amount of heat, and consequently makes the bodies from which it rises colder as it proceeds. If the surface of a pool is giving off vapour, the remaining mass of water is made colder by the action; and if a wet cloth gives off its moisture, the cloth is cooled through the loss of the heat which the rising vapour carries off: the more intense the evaporation, the greater will the cooling be. In applying this principle to measure the humidity contained in the air, two thermometers are taken—one of the ordinary construction, which serves simply to give the temperature of the air; but the other has its bulb covered with a piece of rag, which is kept constantly wet by communicating with a cup of water by an absorbent wick. The water round the bulb will be constantly evaporating when there is any dryness in the air; and the greater the dryness, the more intense the evaporation, and consequently the greater the cooling of the bulb, from which the rising vapour derives its latent heat. Hence this moist-bulb thermometer will fall in proportion to the degree of the evaporation, or in proportion to the dryness of the air at the time. We have therefore only to compare the two thermometers—the one giving the air's temperature, and the other a reduced temperature depending on the rate of evaporation or the degree of thirstiness—in order to judge of the comparative quantity of moisture existing in the surrounding atmosphere. Tables are used along with this hygrometer for calculating the dew-point temperature, which is ascertained, without calculation, by Daniell's instrument. The advantage of the wet-bulb hygrometer is, that an observation can be made without much trouble; whereas a nice operation must be performed upon the other in order to obtain what is sought.*

The force of evaporation, or the quantity of water which is converted into invisible vapour in a given time, depends entirely upon the dryness of the air, or upon the vacancy for moisture that exists at the time; this vacancy being measured, as we have already shewn, by the difference between what might exist and what does exist. For example, it is calculated that if the air were at 60°, and the dew-point 40°, about a quarter of a grain of water would rise every minute from a surface of six inches diameter. But no calculation of this kind is

* Besides the above, there are various instruments called *hygrometers*, depending on the principle of the shrinking and expanding of bodies in relation to the degree of humidity with which they are affected. Fibrous vegetable substances, such as ropes, contract by imbibing moisture; while, on the contrary, hairs and catgut (strings of violins) contract by drought. Hair has been found to be the most delicate in hygrometrical motions. Saussure accomplished the construction of a hygrometer from a single long hair, previously cleaned in a soda lye. Various philosophical toys, as ornaments for mantel-pieces, have also been constructed to indicate the dryness and moistness of the atmosphere, all on the similar principle of contraction and expansion of a hair, piece of catgut, or part of the beard of the wild oat. One of the most useful instruments of this class is a small object resembling a watch in external appearance, designed to prove the dampness or dryness of beds: a movable hand on the dial-plate points out very speedily the hygrometrical condition of the bedclothes on which the instrument is laid. Hygrometers of the kind just mentioned, however ingenious, fail as instruments of science or of rigid comparison, chiefly from the circumstance of their liability to lose their contractile and expansive energy, as well as the difficulty of making many of them to possess similar powers.

as yet perfectly accurate, owing to the uncertain action of the wind on evaporation. The effect of a current of air, is to carry off the vapour from the surface as it rises, and leave the space free for an additional supply. The more rapid the wind, the faster every wet surface dries up. On calm, stagnant days, drying is in general a very slow process compared with its rate under a brisk wind.

If there were no other atmosphere upon the earth than the atmosphere of vapour, and if the whole surface of the earth were at 32°, the constitution of such an atmosphere, in respect of pressure and temperature at different heights, would be, according to Professor Daniell, as in the following table; in which it must be noticed that the numbers for the elasticity of vapour are somewhat different from the table given at page 36, which is taken from the one in use at Greenwich Observatory:—

Height in Feet.	Elasticity or Pressure in Barometric Inches.	Temperature.
0	·200	32°
5,000	·177	28·5
10,000	·157	25
15,000	·140	22
20,000	·124	19
25,000	·110	16
30,000	·100	13

If we compare this table with the similar one previously given for dry air, we find one striking discrepancy, and that is in the decrease of temperatures. The decrease in the vapour is very slow compared with that of the dry gas. At 5000 feet, the dry air sinks from 32° to 14°·8, or about 17°, while the vapour falls only 3½°. At 20,000 feet, the dry air is as low as —43°, or has descended 75°: at the same height the vapour has descended only 13°, or to from 32° to 19°. The same contrast is seen whatever be the commencing temperature. This disparity produces very important consequences, seeing that the two atmospheres are mixed up together.

The same relation subsists between the vapour of the atmosphere and the other two gases, nitrogen and oxygen, that compose it, which holds between these two gases themselves; that is, the particles of elastic vapour repel one another, but do not seem to repel the particles of nitrogen or oxygen; consequently, while they must keep their distance from their own kind, they may freely approach and remain near the particles of the other kinds. If the particles of oxygen are, in consequence of their smaller quantity, more widely apart than those of nitrogen, the particles of water may be supposed to be much further apart than either; for the steam in the air is but very small in amount compared even with the oxygen. We are to conceive, therefore, a very wide-spreading set of vapoury atoms moving about in a space where there also floats two other sets of atoms, both of them much more numerous than the atoms of vapour. Although there is no repulsion between the atoms of different kinds, there may, however, be an attraction: it is possible that when a particle of steam comes near to a particle of oxygen, they may cohere, and remain until something happen to separate them.

Professor Daniell has traced very important consequences to the disparity of the decrease of temperature in the two atmospheres of dry gas and vapour. We have seen, for example, that at 5000 feet the decrease of temperature of the dry air is from 32° to about 14°; and that the decrease in the steam atmosphere by itself would be only to 28°. Now as this steam at 28° exists in the midst of the air at 14°, it will necessarily be cooled down, by the influence of the cold mass, to the same pitch as the air, or to 14°; but with this cooling a precipitation must take place, for the amount of steam that could exist at 28° cannot be maintained at 14°, and all the surplus will therefore be thrown out as visible cloud, and fall downwards to the lower regions. At some still higher stratum, the same process will be again repeated; for, notwithstanding the amount thrown out at the first stage, what remains will at some high station be found too much for the surrounding temperature, and a fresh precipitation in the form of cloud will occur.

Hence it will happen that although evaporation is going on abundantly in the lower regions, and the temperature such as to sustain it in the invisible form at the earth's surface, yet when it rises upwards, it will come to some stratum too cold for it, and where, therefore, a certain portion must be thrown out of the invisible into the visible state, and cause a cloudy layer to be formed. Above this the air will perhaps be clear for a considerable way, but at a certain additional height, the same excessive coldness will occur, causing a succession of cloudy layers. The greater the dryness of the lower air, the further up will the clear region extend, or the higher will be the first place of deposition or cloudiness.

When invisible vapour, or true steam, is precipitated either into water or into the intermediate state of cloud, its latent heat is given out; that is to say, all the heat that entered into it when it first passed from water into steam. In the case of a precipitation in the upper air, all the heat is communicated to the air, and serves to raise its temperature to some extent. Now, we have seen that this is one of the cases where the upper-current of the atmosphere may be increased without a corresponding increase in the under-current, and where, consequently, the total pressure will be altered. If the air is heated and expanded in the upper regions while remaining unaltered below, the overflow or passing away of the upper air will be increased, while the influx beneath continues the same, and consequently more will be going away than there is coming in, so that the whole column will be lightened. In this case, the barometer must fall, and a corresponding rise will occur in some other places; hence a great degree of evaporation, or a very great quantity of vapour in the air, is apt to make the barometer stand low. The currents of dry air formerly mentioned do not tend to disturb the barometer; the prime cause of all its fluctuations lies in the actions of the vapour, which alter the natural gradation of temperature and pressure, by carrying heat from the surface to discharge it in the higher regions.

We must now allude more particularly to the peculiar forms of visible vapour, or the constitution of the varieties of watery substance named mist, fog, cloud, dew, hoar-frost, rain, snow, and hail. Mist, fog, and cloud are names for nearly the same thing. When there is a general haze of precipitated vapour covering the whole sky, and coming down to the surface of the earth, it is termed a *fog*. When a white smoke is seen to rise from the courses of rivers and wet land, it is called a *mist;* but mist and fog are often indiscriminately applied to the same appearance—namely, to a vapoury haze lying upon the ground. *Clouds* are the masses of haze or fog which are seen floating in the higher regions, and which do not descend to the ground.

It being well known that visible vapour, cloud, or mist is not elastic or gaseous, and therefore is not supported by its expansive force like a gas, it has been always a mystery how the clouds are kept suspended in the air. When steam is precipitated into white watery particles, they ought to fall to the ground immediately like a shower of dust; for they are no longer supported by being repelled upwards by the particles beneath them. Many explanations have been devised for this singular fact. It has been supposed that the particles of cloud are like blown bubbles, which are lighter than the air, and therefore supported like balloons. But if they were little balloons, they could hardly be so perfectly balanced as never either to float upwards or sink downwards. Besides, no man can say how such watery vesicles can come to be filled with a gas lighter than the air surrounding

them. The only explanation yet given which is consistent with the known facts, is, that the watery particles are suspended by their adhesion to particles of air. We are quite entitled to suppose that a particle of water has an adhesion to a particle of air when they encounter one another in the atmosphere, just as we are sure that water on the ground has a strong attraction for the air in contact with it, or contained within its mass. This attraction upholds the vapoury particles when they are bereft of the self-sustaining power of elasticity or mutual repulsion.

The steam of a kettle when it becomes visible, the white cloud of a steam-chimney, our breath in a moist or cold day, are all precipitated moisture or mist. Sometimes this mist is rapidly reabsorbed as it spreads out, shewing that there is a certain dryness or vacancy in the air sufficient to take it in among the invisible steam, when it is distributed over a somewhat larger surface.

If the air is exposed to a cooling, so as to bring it beneath the temperature of the dew-point, vapour must be thrown out everywhere, and a fog or mist will be formed. If, for example, the dew-point were 45°, and if a cold wind or the decline of the day were to sink the air to 32°, then all the moisture above what can remain at 32° would be made visible, and a very dense fog would be the result. In this manner are formed the dense fogs of the polar seas, the fogs found along the courses of rivers, upon the sides of mountains, and over shoals and headlands. The difference between the temperature of the water and the adjacent land affects of course the air resting upon them; and hence the development of visible vapour in these localities.

The celebrated fogs of London originate in the same way; but their black and thick appearance is owing to the quantity of smoke which is suspended in them. Water in every shape has an intense attraction for carbon; and the particles are strongly seized upon by the precipitated vapour, and detained to blacken the atmosphere. This attraction would seem to prevent the ready absorption of the fog, even in the dry air of rooms. In towns where little smoke is produced, the peculiar black fogs of London never arise. The great attraction of water for almost all substances is one cause of the disagreeable effects of mists and fogs; for the effluvia that would otherwise rise upwards and diffuse themselves, are to a great extent caught and held by the free vapour, and thus kept near the surface. In stagnant foggy days, all the odours which arise from houses and works are more perceptible than at other times.

Clouds have been distinguished by Mr Howard into several classes, according to their structure and appearance. The three principal forms are the *cirrus*, or feather-cloud, the *cumulus*, or heaped-cloud, and the *stratus*, or stretched-cloud. The *cirrus* is composed of

Cirrus.

thin threads or filaments, aggregated into woolly or feathery forms, and sometimes making a delicate slender net-work. It is the first indication of serene and settled weather, and first shews itself in a few fibres, spreading through the atmosphere. These fibres by degrees increase in length, and new fibres attach themselves to the sides. The duration of the cirrus is uncertain—from a few minutes to several hours. It lasts longer, if it appears alone, and at a great height; a shorter time, if it forms in the neighbourhood of other clouds. From its usually curling appearance, the cirrus is called in England the *mare's-tail* cloud. The *cumulus* is the kind of cloud resembling mountains piled upon mountains, and generally ends above in rounded masses, while it is horizontal

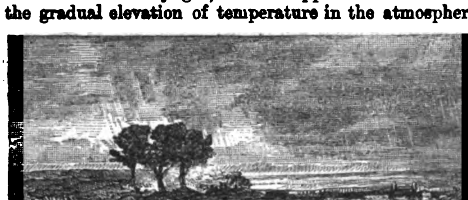
Cumulus.

below. The appearance, increase, and evanishing of cumulus, in fine weather, are often periodical, and correspondent to the degree of heat. Generally, it forms a few hours after sunrise, attains its highest degree in the hottest hours of the afternoon, and decreases and vanishes at sunset. If the upper region, with its drying power, predominates, the upper parts of the cumulus become cirrus; but if the lower region predominates, the basis of the cumulus sinks, and the cloud becomes *stratus*,

Stratus.

which appears as a long horizontal band of moderate density, with its lower surface resting upon the earth or the water. Combinations of the above forms have been discriminated under the names of *cirro-cumulus*, *cirro-stratus*, and *cumulo-stratus*. The black rain-cloud, which seems a general mixture and confusion of all the clouds in the heavens, has been called the *nimbus*.

The *cirrus* clouds are the most elevated: they have been found as high as 20,000 feet, and they must therefore be often made up of snow-particles, for even under the equator, water would be frozen at such a height. In general, we may say of the light fleecy masses that we see on a summer-day, that they are made up of snow-powder or frozen particles. The *cumulus* clouds are evidently the precipitation of the ascending vapour in the cold upper regions; for they generally increase with the heat of the day, which disperses all superficial mists. The *stratus*, on the other hand, has more the character of a night-cloud: it is a result of the cooling of the air in the evening, and comes out in the lower regions of the atmosphere. All mists and fogs are of this species of cloud, which, in its lightest state, does not wet leaves or any objects with which it comes in contact. In calm evenings, the stratus may be seen ascending from the valleys to the higher grounds, and there extending itself in masses like a fleecy mantle. It generally arrives at its point of greatest density about midnight, or between that time and daylight, and disappears at sunrise by the gradual elevation of temperature in the atmosphere.



Nimbus.

Sometimes it remains quiet, and accumulates in layers, till the atmosphere is incapable of sustaining its weight,

when it assumes the condition of the heavy and dark *nimbus*, and falls in a shower of rain.

When moisture is precipitated at night in the form of wetness and drops on the surface of the ground and on the leaves of plants, it receives the name of *dew*. This precipitation arises when the surface of any body is cooled below the dew-point temperature. Thus, if the dew-point were 45°, and if by any means a glass tumbler were cooled down to 40°, the film of air lying next to it would also be cooled down to 40°, and would therefore have to give out all the vapour which it could not hold at that temperature; but the precipitated surplus in this case would not appear as mist in the air, but would adhere to the surface of the glass. When cold glasses are brought into a warm room, they sometimes become dewed all over in this way. The bringing out of visible dew is, as we have seen, the means of determining the dew-point temperature in Daniell's hygrometer.

Night-dews are most copious when the sky is clear. The reason of this is, that the earth cools faster under a clear sky than when hung over with dense clouds, which prevent the radiation of the heat; just as bed-curtains make a bed warmer. The surfaces which naturally radiate off their heat with most rapidity are the first to sink below the dew-point temperature and to become dewed. Thus, rough surfaces are wetted sooner than smooth, plants sooner than glass, and glass sooner than metals. Metals being good conductors of heat, as fast as their surface cools, heat flows to it from the interior, and consequently the temperature of the surface cannot sink till the whole mass throughout has parted with its heat. Woolly and fibrous substances cool very fast at the surface, and are therefore rapidly bedewed. No dew can fall on a surface till its temperature has fallen below the dew-point; hence in the case of a very dry atmosphere there may be no dew formed at the coldest time of the night. In arid deserts, and in the countries where dry winds prevail, dew is not often seen.

When the surface dewed is below the freezing temperature, the vapour is not only precipitated, but is also frozen; hence the origin of *hoar-frost*, or frozen night-dew. The occurrence of hoar-frost is a proof that the temperature of the ground has fallen below 32°, as well as below the dew-point temperature. As in the case of dew, everything that prevents the radiation of heat arrests the formation of hoar-frost. During the chilly nights of spring, plants that are sheltered by trees are less liable to be frozen than those which are fully exposed; and a slight covering of straw, or even of paper or netting, will often afford an effectual protection. Vineyards, it is said, have frequently been saved from the effects of frost by enveloping them during the night in a cloud of smoke.

Rain is the aggregation of the cloudy particles into masses or drops, which can no longer be sustained by adhesion to the particles of air, and must therefore fall to the ground. Rain most usually arises from the mixture of different strata or currents of air. When a warm saturated mass is acted on by a cold mass, there is always a precipitation of vapour; and besides this, the agitation and conflict of the two currents bring the scattered particles nearer each other, so as to favour their adhesion. As the amount precipitated increases, the aggregate drops will become larger, and at last they will fall away by their own weight.

When the temperature of the stratum of air from which the rain falls is under 32°, the vapour or clouds must necessarily be frozen, and the descending particles will be *snow* instead of rain. Snow-flakes are the aggregation or union of frozen particles, just as rain-drops are the union of watery particles. They aggregate, according to the law of the crystallisation of water, into regular and symmetrical forms, of which the general character is a six-sided figure; as, for example, six needles branching from a centre, or six arms from a six-sided nucleus, each needle being three or six sided. Though single crystals always unite at angles of 30°, 60°, or 120°, they nevertheless form, by their different modes of union, several

hundred distinct varieties of snow-flake, some of which are figured in the preceding engraving. Any agitation of the air, or an increase of moisture or temperature, destroys of course their delicate and beautiful structure.

When drops of rain formed in an upper stratum descend through a stratum whose temperature is less than 32°, they are frozen into lumps or balls of ice, which we term *hail*. Hailstones are thus the consequence of an irregularity, or an exception to the ordinary and natural arrangement of the atmospheric layers: instead of the colder air being always uppermost, in this case a cold must lie beneath a warm stratum.

The precipitation of vapour in any shape, causing a vacuity, as it were, in the atmosphere, is generally accompanied with commotions and rapid movements of the air, which are called *storms*. These differ from the ordinary wind-currents in being sudden, violent, and temporary.

Besides *nitrogen*, *oxygen*, and *watery vapour*, the atmosphere contains *carbonic acid* to the amount of about a two-thousandth part of its whole weight. This is employed by nature, along with water, in supplying the food of plants; and it is given out in the processes of combustion and animal respiration. It is diffused through the other gases of the atmosphere on the principles already laid down. *Ammonia* is also a constituent of the atmosphere, but its amount is exceedingly small. These may be said to be all the permanent elements of the atmosphere, or the substances always present in it, and diffused through its whole extent.

From its contact with the earth, the lower stratum of the air usually contains a number of casual substances: such as the gaseous exhalations from animals and vegetables, living and dead; the exhalations from all chemical and organic processes, whether natural or artificial; the innumerable gaseous and volatile products of human habitations, villages, and cities; the odours and effluvia that issue from almost every spot of the earth; the sand, dust, and fine solid particles which are carried up from the surface, and floated in the winds; the seeds of numerous plants and animalcules, which, by their minuteness and lightness, are easily carried in the air; and the subtle matters that convey the poison of disease. Most of these substances, from their injurious effect on the human system, are regarded as impurities; but their consideration does not belong to meteorology.

SURFACE OF THE EARTH IN RELATION TO THE ATMOSPHERE.

Mean Temperature—Trade-winds—Sea and Land Breezes—Hygrometric Changes—Fall of Rain—Fluctuations of the Barometer and Thermometer.

The changes and fluctuations of the atmosphere have all a relation to the peculiarities of the earth's surface, and especially to the unequal heating of its different parts, owing to the varied action of the sun, the distribution of sea and land, and the different elevations of the land. The decrease of heat from the equator to the poles causes one class of atmospheric changes; the change of the sun's place in the course of the year, or the rotation of seasons, causes another class of changes; and both of these are modified by the positions of sea and land, and by the characters of the mountains, valleys, and plains of the land-surface.

The mean temperature of the equator is about 81°. If the whole earth were a perfectly smooth globe of one uniform kind of surface—that is, if it were all sea, or all

one kind of level land—the temperature would decrease steadily from the equatorial amount, according to the latitude. The mean temperature at the poles cannot be known by actual measurement; but it is inferred to be about 10°. The poles, however, appear not to be the coldest points of the globe. In the northern hemisphere there would seem to be two poles of maximum cold, about latitude 80°; the one north of Siberia, the other north of America.

By the *mean temperature* of a place is understood the average temperature for a whole year, or for a number of years. If observations were made of the temperature for every hour in the course of a day, the average of all these would be the mean temperature of the day; also the mean of the greatest and least temperatures would be pretty nearly the mean of the day. If the mean temperatures of 365 days are found in this way, and an average taken of the whole, this gives the average or mean temperature of the year. And if a great many years have been observed in the same manner, the average of the whole would be reckoned the general mean temperature of the place where the observations have been made.

The action of the sun is the chief source of the warmth possessed by the atmosphere and the ground, though not the only source. The earth itself is proved to have a permanent internal heat, which increases gradually from a point beneath the surface downwards, as far as observations can reach. But the heat that fluctuates from day to day, and which is greater in summer than in winter, and in the daytime than during the night, is derived solely from the sun; and these variations are owing to his acting more strongly at one time than at another.

The reason why the sun heats the equator and the regions adjoining more strongly than it heats the temperate and polar regions, is, that at the equator it rises higher in the heavens, and shines more directly downwards. The further away a place is from the equator, the less is the average noonday height of the sun, and therefore the smaller the influence it exerts.

The whole force of the sun's rays does not act directly on the solid surface of the earth; the atmosphere arrests a certain portion of the heat, and is itself rendered warm by the portion arrested. This is one source of the warmth of the air. When clouds are spread out in the atmosphere, the resistance to the rays is still further increased, and a greater portion taken up by the air itself. The other sources of atmospheric heat are, contact with the surface of the earth, and the radiation of heat from the ground upwards.

The air exercises a very important influence in keeping up the mean temperature of the earth, by resisting the passage of heat outwards, on the same principle that our bodies are kept warm by clothing. The thinner the covering of air, the colder would the earth be; as we see in ascending to the tops of mountains, at which the temperature is always much lower than at the sea-level—the cold increasing with the height. These high places receive a more intense solar radiation through the thin covering of air that lies upon them; but such is the ease with which the heat can radiate off through a thin atmosphere, that they are always kept comparatively cold. If we had no atmosphere at all, the rays of the sun would be very intense where they actually struck, but so rapid would be the loss of heat by radiation, that the whole earth would be permanently kept far below freezing; no liquid material of any known kind could exist on its surface.

The first great effect on the atmosphere of the unequal temperature of the different parts of the earth, and especially of the steady decrease of heat from the equator to the poles, is to produce the two grand currents which we have already described: an upper-current from the equator to the poles, and an under-current from the poles to the equator. If the earth were at rest, these currents would blow exactly north and south, but the daily revolution of the globe has an effect in altering their directions. The equator, or thickest portion of the earth's body, considered as a ball revolving on an axis, moves with the greatest rapidity in the daily whirl; any place upon it is carried round at the rate of upwards of 1000 miles an hour. But the belts on each side of the equator being smaller in circumference, any point on one of them is moved with proportionably less rapidity. Thus the belt or zone at 60° of latitude has only half the circumference of the equatorial zone, or about 12,000 miles; so that a place upon it will move round only 12,000 miles a day, or 500 miles an hour. In like manner, at 30°, the rapidity of movement is about 860 miles an hour. Now the atmosphere revolves along with the earth, and every portion of it will have the same velocity as the place on which it lies. Thus the equatorial atmosphere will have a motion with the earth of 1000 miles an hour, and the atmosphere at 60° will have a motion of 500 miles an hour, from west to east. But if the equatorial air, with its high velocity, is carried away in the upper-current to a place with a lower velocity, the air will still persevere in its equatorial speed, and will consequently outrun the speed of the place upon which it has come, and be felt as a strong wind in the direction of the rotation. If equatorial air were suddenly transplanted to 30° latitude, for example, it would be moving from west to east at the rate of 1000 miles an hour, over ground whose movement would be only 860 miles an hour; or the air would outrun the ground, or sweep over it at 140 miles an hour. This would have the effect of a westerly breeze of this degree of rapidity, and as such it would be felt by the inhabitants.

A similar explanation serves to shew that the under-currents from the poles to the equator will not be due north and south, but will have, in addition, a direction towards the west. Air from latitude 30° going upon the equator with an eastward velocity of 860 miles an hour, will move 140 miles an hour slower than the equatorial surface, or it will lag so much behind; and the effect will be felt as an easterly wind sweeping over the surface at this rate.

According to this simple theory, the prevailing winds ought everywhere on the earth's surface to be easterly: in the northern hemisphere, they should blow from the north-east; in the southern hemisphere, from the south-east. And within the tropics, and to some distance beyond them, this is in fact the case. The great polar currents are there known by the name of the *trade-winds*, because they are so constant that they can be calculated on by navigators. The trade-winds begin to be felt at about 30° of latitude on each side of the equator. Ships entering upon this belt begin to feel a steady easterly breeze, which continues, although with some variation, to within 2° of the equator. The two currents from north and south meet about the equator, and completely neutralise each other; and their meeting forms a belt varying from 150 to 550 miles in width, called the *region of calms and variables*. There is no steady wind in this region; its atmosphere is generally calm, having at certain seasons light southerly winds, interrupted by fearful storms and tornadoes.

Beyond the region of the trade-winds, the prevailing currents are in the opposite direction—in the northern hemisphere, for instance, from the south-west. To account for this, we must suppose that the two great currents change places, and that about the latitude of 30° the equatorial current descends to the surface of the earth. The annexed figure represents the way in which Lieutenant Maury conceives the air to circulate round the globe. 'Setting off from the north polar regions, a particle of air, for some reason which does not appear to have been very satisfactorily explained by philosophers, instead of travelling on the surface all the way from the pole to the equator, travels in the upper regions of the

atmosphere until it gets near the parallel of 30°. Here it meets, also in the clouds, the hypothetical particle that is coming from the south, and going north to take its place. About this parallel of 30° north, then, these two particles press against each other with the whole amount of their motive power, and produce a calm and

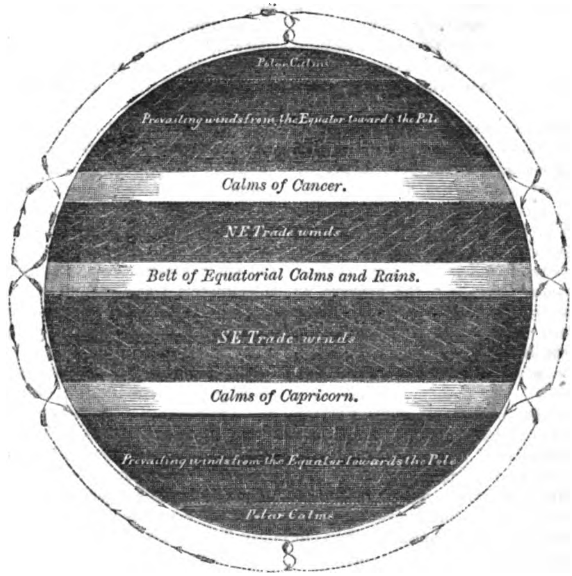


Diagram of the Winds.

an accumulation of atmosphere: this accumulation is sufficient to balance the pressure of the two winds from the north and south. From under this bank of calms, which seamen call the "horse-latitudes" [Calms of Cancer, in the diagram], two surface-currents of wind are ejected—one toward the equator, as the north-east trades, the other toward the pole, as the south-west passage-winds.'

The region of the south-east trade-winds is much larger than that of the north-east, the belt between them lying generally not at the equator, but several degrees north of it. The entire belt of the trades shifts in some degree northwards in summer, and southwards in winter, following the course of the sun.

Direct proofs have been furnished that in the regions of the trade-winds there are upper return-currents flowing in the contrary direction. The ashes of the volcano of St Vincent, on one occasion, were carried from west to east, to the astonishment of the inhabitants of Barbadoes, who were experiencing at the time the easterly wind. More striking still is the evidence furnished by the showers of dust, of a brick-red colour, that often fall on ships about the Cape de Verd Islands and in the Mediterranean. It was supposed to be brought from the parched deserts of Africa; but Ehrenberg, with his microscope, has shewn it to consist of infusoria and other organisms, belonging not to Africa but to South America. It would appear to be raised from the parched plains by the tornadoes of the equinoxes, and wafted by the upper-current across the Atlantic.

The great polar and equatorial currents are modified by another class of currents, of a more local and limited character, arising from the distribution of sea and land, and the unequal susceptibility of these to the sun's heat. If the sun shine with the same directness and force on two tracts of surface, the one water, and the other solid ground, the ground will be most rapidly heated, and at the end of the day it will be found much warmer than the water. On the other hand, in the absence of the sun, the land cools fastest, and at the end of the night it will be found below the temperature of the adjoining water. This difference causes an inequality in the temperature of the columns of air lying upon the two surfaces. When the land is hottest, the air resting upon it will be hotter and more expanded upwards than the air over the sea; hence the cold air from the sea will rush in upon the hot in the lower regions, and the hot will fall in upon the cold above. Thus during the day, when the land is warmer than the sea, there will be a breeze from the sea to the land, and during the night a breeze from the land to the sea. These are called the *sea and land breezes.* They rise regularly on all the sea-coasts. In calm weather, or when not overborne by other winds, they may be always observed. The sea-breeze, or the current from the sea to the land, begins at about eight or nine in the morning: at first it is gentle, and extends only to a short distance; it gradually increases, both in force and in extent, till about three o'clock in the afternoon, when it begins to decrease, and gradually to give place to the land-wind, which rises soon after sunset, and attains its greatest force in the morning.

On coasts where a large tract of land joins a great expanse of sea, as on the coasts of America and the south of Asia, the sea and land breezes become very considerable. The easterly trade-winds are often reversed by them. But the most powerful effect of the sea and land winds is annual, or dependent on the seasons. The most remarkable example of this is furnished by what are called the *monsoons*—from the Malay word *moussin*, signifying seasons—experienced along the coasts of Africa, India, and China. When the sun is far north in midsummer, and shines with direct rays on the Asiatic peninsulas, the land in them is rendered very much hotter, both day and night, than the ocean, and a strong sea-wind sets in towards these coasts from the south-west—that is, in a direction opposite to the great current that causes the trade-winds. Hence an immense wide-spreading conflict arises, which begins about the month of April, or two months before the sun has reached his extreme north declination. The first beginning of the conflict in April causes furious rain, wind, and thunder-storms; but in the course of two or three weeks the sea-breeze completely overcomes and suspends the trade-wind, and continues steadily to prevail from April to October; this is called the *south-west monsoon;*

and it can be as much calculated on for navigation as the trade-winds in their most uninterrupted regions. The influence which sustains this wind becomes gradually weaker as the sun moves southward, and in October it becomes too weak to overcome the trade-wind, and the two meeting with equal force, cause a second violent tumult of rain and storms, till in a short time the trade-wind prevails; which then continues during the winter half-year, and forms what is called the *north-east monsoon*.

In the Atlantic, a similar action is perceived. In the summer-time, the land of North Africa is made so much hotter than the adjoining sea, that a brisk south-west or south-south-west wind blows between the equator and the southern limit of the northern trade, which is then at about 10° or 12° north latitude. In America, also, similar breezes are experienced.

The chief sources of evaporation are the seas, lakes, and rivers: from these the moisture rises and diffuses itself over the land; and in general it must happen that the air lying on the seas and lakes must be more highly charged with watery vapour than the air lying on the land. The interior of continents will therefore be much drier than the sea-coasts. Between the valleys of the Irtish and the Obi, Humboldt found, after the winds had blown for a long time from the south-west, from the interior of the continent, that with a temperature of 75°, the dew-point was at 24°, giving a dryness of about $\frac{1}{10}$ths of an inch.

Although there is three times as much sea as land, this is not more than enough to keep up a sufficient moisture for the habitable countries; for although some regions have rather more than is desirable, many large tracts of country remain desert and uninhabitable solely from the dryness of their air and the scarcity of rain. If there had been as much land-surface as water, a far less portion of the globe would be habitable than at present.

The evaporation is necessarily greatest in the equatorial regions, where the temperature is greatest, and decreases steadily towards the poles. For the same reason, the precipitation of vapour, or the rain, must be most abundant in the warmest climates, and in the neighbourhood of the tropical seas. On the Malabar coast of the East Indian peninsula, at 11½° from the equator, the fall of rain in a year amounts to 123 inches, or to a lake of water 10 feet deep. In latitude 60°, the fall is reduced to 17 inches. In Great Britain, the annual fall is from 20 to 40 inches.* The quantity of rain on high grounds is often greater than at the sea-level, especially on mountains that stand in the way of moist winds. At Geneva, the annual fall is about 31 inches; at the Great St Bernard, it is 60 inches. At some places among the mountains of Cumberland, upwards of 100 inches fall, while in the plains to the east of them the fall is not greater than from 20 to 24 inches. These mountains interrupt the highly charged winds from the Atlantic, and receive a considerable portion of their vapour, rendering the air drier over the inland counties than at the sea-coast. In general, when a mountain-chain crosses the course of an ocean-wind, the weather-side is wet and the lee-side is dry. The trade-winds of the Atlantic sweeping over the continent of South America become cooled as they ascend towards the Andes, and, depositing their vapour, feed the mighty streams of the Amazon and Orinoco. On the west side of the wall of the Andes, in Peru, rain is almost unknown.

The greatest fall of rain on record is perhaps that observed by Mr Yule at Churra, north-east of Calcutta, among the Khasian Mountains. In the single month of August there fell 264 inches, of which 150 inches fell in the space of five consecutive days. Another observer at the same station measured 500 inches in the space of seven months. The cause of this unusual rain-fall is attributed to the abruptness of the Khasian Mountains, which face the Bay of Bengal, and intercept its moist winds.

Rain does not often fall in the constant trade-winds, owing chiefly to the steadiness of temperature. These constitute the great evaporating regions. But when the equatorial air, with its high temperature and high charge of vapour, goes some way into the cold latitudes, it is reduced in temperature, and can no longer contain its entire load of moisture, and rainy precipitations must ensue. Thus a constant distillation is going on from the tropical seas towards the regions without the tropics on each side. Hence, as a general rule, south winds with us are moist and rainy, and north winds are dry.

The daily and yearly courses of the sun cause daily and yearly fluctuations of the temperature, moisture, and pressure of the atmosphere; or in the thermometer, hygrometer, and barometer, which measure these fluctuations.

With regard to *temperature*, the *daily* fluctuation follows the career of the sun. It is lowest, or at a *minimum*, a little before sunrise, and it increases gradually from this time till two o'clock in the afternoon, when it is generally at its highest or a *maximum*. Although the sun is most powerful at noon, yet his effect in heating the earth does not attain its highest amount till about two hours after.

In the *annual* fluctuations of temperature, we find a similar course of rise and fall: there is an increase to a maximum in summer, and a decrease towards a minimum in winter. The intensity of the sun's rays is greatest in June, but the greatest heat occurs in July, or about a month after the longest day. In Paris, the highest temperature has been observed to happen on the 15th of July, and the least on the 14th of January. The days whose temperature is the mean or average of the whole year are about the 22d of April and the 20th of October.

The fluctuations of *vapour* follow the changes of temperature. As the temperature rises, evaporation increases, and the amount held in the air becomes greater. On the other hand, the diminution of the temperature leads to precipitations, and lessens the amount of the steam atmosphere. As the sun ascends in the heavens each day, the evaporation is promoted, and the absolute quantity in the air is increased; but this additional portion being very small in proportion to the whole increase of temperature, the actual dryness of the air is also increased until the maximum of heat has been attained. With the decline of the day the dryness diminishes, without a diminution of the actual amount of vapour, until the air cools down to the dew-point, when precipitation must begin. The dew-point temperature is every night sunk at least as low as the least temperature of the night.

The dryness of a day depends on the difference between the highest temperature of the day, and the least temperature of the night before; thus, if the maximum day-temperature were 60°, and the minimum of the previous night 40°, the dryness would be very considerable. But if the least temperature of a given night, and the greatest temperature of the next day, are very nearly equal, the air will be almost saturated with moisture the whole day. Thus dryness depends on cold nights preceding warm days. This rule, which connects the lowest temperature at night with the dew-point of the following day, may be violated by such accidental causes as the flowing in of warm, cold, or moist air, to change the character of the place. In

* The quantity of rain which falls at any station during a given time is ascertained by means of the *rain-gauge*—an instrument constructed in various ways. One of the simplest forms consists of a cylindrical copper vessel furnished with a float: the rain falling into the vessel raises the float, the stem of which is so graduated that an increase in depth, to the extent of one-hundredth of an inch, can be ascertained.

spite, however, of such casualties as these, the rule is generally true, and is very important in its applications, to inform us of the state of the air in respect of moisture, by means of the thermometer alone. If we take the lowest temperature of a night, and the average or mean temperature of the next day, the difference of the vapour sustainable at each will give the average dryness of that day. Thus if the minimum at night were 35°, and the average of the day 42°, then

Vapour at 42°, ...	·283 inch.
〃 35, ...	·222 〃
Dryness, or capacity for additional vapour,	·061 〃

Again, if the average temperature were 60°, and the lowest temperature 45°:

Vapour at 60°, ...	·523 inch.
〃 45, ...	·315 〃
Dryness, ...	·208 〃

In this last case the dryness is more than three times as great as in the other. And to prevent mistakes, it must be remembered that a difference of a certain number of degrees will cause a much greater dryness at a high temperature than at a low. Thus let us compare the extreme dryness of a winter and a summer day, on the supposition that in both cases the greatest range of the thermometer is 20°. Let the lowest temperature of the summer-day be 50°, for example, and the highest 70°:

Vapour that could be contained at 70°, .	·727 inch.
〃 〃 〃 50, . . .	·373 〃
Difference, or extreme dryness of the day,	·354 〃

Again, let the lowest temperature of the winter-day be 30°, and the highest 50°:

Vapour that could be sustained at 50°, .	·373 inch.
〃 〃 〃 30, . . .	·192 〃
Difference, or extreme dryness of the day,	·181 〃

Thus the dryness of the winter-day is only half that of the summer-day, although they have both the same range of 20°. And if we consider that a range of 20° is very often attained in summer, and very rare in winter, in a country like ours, we can judge what an immense difference there must be between the two seasons in point of dryness.

With regard to the fluctuations of *atmospheric pressure*, as shewn by the rise and fall of the barometer, it is found that between the tropics these fluctuations are very small, not extending to much above a quarter of an inch; but beyond the tropics they are very great, and the barometer has a range of three inches. The abundant aqueous precipitations which take place on each side of the tropics are the cause of these extensive fluctuations.

The barometer has in all places a regular daily fluctuation. From mid-day it falls until between three and five in the afternoon; it then rises again till between nine and eleven in the evening. It falls again to a second minimum about four in the morning, and rises to a second maximum about ten in the morning. The hours are not exactly the same for all countries, and the extent of variation is also different in different places, but the rise and fall twice in the twenty-four hours is a universal occurrence. The extent of the fluctuation diminishes as the latitude increases, according to a regular law. At Edinburgh, it is, on the average of the whole year, about $\frac{1}{100}$th of an inch; near the equator it is about ten times as great. There can be no doubt that these variations are connected with the daily variations of temperature and vapour arising from the course of the sun, but the exact way in which they are produced is not very clearly understood.

As we ascend in the air above the sea-level, or descend into the earth beneath it, we find a change of temperature. In ascending, the air becomes colder, at the rate of one degree of the thermometer to about 352 feet of ascent; the decrease of temperature being somewhat greater in high than in low latitudes, and not so much at great heights as near the earth's surface. The causes of this have been already explained. At a certain height over every place, water will freeze, and if a mountain rise to this height, it will be covered with snow. The height over any place where water must be frozen at all seasons is called the *snow-line*, the altitude of which is greatest at the equator, and diminishes as the latitude increases. At a certain high polar latitude it reaches the mean sea-level; that is to say, the ground at that level is eternally clad with snow.*

When we descend into the depths of the earth, by digging wells or mines, we find also a variation of the temperature. The influence of the sun is extinct about 100 feet below the surface. The difference between the day and night temperatures disappears at the depth of four feet; and the influence of summer and winter vanishes at about sixty or seventy feet, at which depth the temperature always stands about the average temperature of the climate; hence the temperature of spring-water proceeding from this stratum may be taken as the mean temperature of the place. At depths less than sixty feet, the ground is somewhat warmer in summer than in winter, but at greater depths the temperature is always the same. This depth, where the influence of season ceases to be felt, is called the *invariable stratum*. Beneath it the temperature increases gradually as we descend, shewing that the earth has a warmth of its own independent of the sun, or what is called its *central heat*.

According to some observations upon the increase of the central heat, it appears that for every fifty-nine feet of descent, the temperature rises one degree—others make the increase more rapid—so that if the temperature of the invariable stratum, or mean temperature of the place, were 52°, a depth of 10,000 feet would give the temperature of boiling-water, which would shew how far down the water lies which comes up in boiling-springs; at 60,000 feet, lead would be melted; and at twenty miles, cast iron would be liquid. We have no means of knowing if the heat increases steadily in this manner to the centre; but it is highly improbable that it should do so. We see, however, that volcanoes can be fed with burning matter, if their craters are connected with a stratum sufficiently deep to have the required temperature.

LAWS OF WEATHER.

Characteristics of Winds—Whirlwinds—Hurricanes—Rains—Storms.

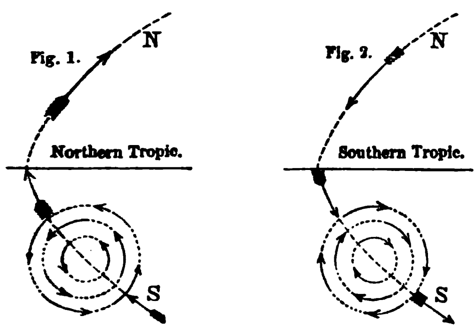
By the laws of weather are understood the fixed relations that have been discovered between the various circumstances of temperature, vapour, pressure, wind, rain, &c. Where such laws, rules, or fixed relations have been ascertained, we can infer one of the things from the presence of its invariable accompaniment, and can thereby often predict heat or cold, storm or calm, rain or dryness, before they actually happen.

We shall consider, first, the various kinds of *winds*, and their laws of connection with temperature, vapour, and pressure. We have already seen the nature of the great equatorial and polar currents, which take the lead of all other winds. The current towards the equator, by coming from a colder to a warmer region, is apt to be

* The *snow-line* is found at various heights, according to latitude, proximity to the sea, and other causes, which affect the general climate of the region. In the Himalaya and Andes, it is found at an elevation of about 17,000 feet; in the Swiss Alps, at 8500 feet; and in the Scandinavian range, at 3500 feet. Generally, in those countries which are near the equator, the snow-line is found about 16,000 feet, or three miles above the sea-level: about the 45th parallel in either hemisphere, it occurs at an elevation of 9000 feet; under 60° of latitude, at 5000 feet or thereby; under 70° latitude, at 1000 feet; and under 80°, the snow-line comes down to the mean sea-level; for countries which are 10° distant from the poles are covered with snow all the year round.

comparatively cool and dry; while the opposite current must be very moist and warm. This great characteristic difference between these two currents is found all over the earth. It is a general rule in our hemisphere, that north-east winds are cold and dry, and south-west winds warm and moist. There are exceptions to this principle produced by the irregularities of land and sea climates, but it is true in the great majority of instances.*

Hurricanes are huge eddies or whirls in the atmosphere, supposed to be produced by the meeting of the upper and under currents in the course of the descent of the upper to the earth, or by a sudden deposition of moisture. They are whirlwinds on a great scale, having two motions, a progressive and a rotary, both following certain fixed laws. Fig. 1, in the accompanying diagram,



indicates the motions of a rotary storm in the northern hemisphere. Originating within the tropics, it travels in a curve, first north-west, and then north-east; while the direction of the whirl is *against the hands of a watch*. In the southern hemisphere, the progressive motion is from the intertropical regions (fig. 2), first south-west, and then south-east, and the rotary motion is *with the hands of a watch*. By taking advantage of this 'law of storms,' a ship may sail out of a hurricane.

A *water-spout* or land-spout seems to be a rotary storm or tornado of narrow dimensions, by which a cloud is thrown into a rapid whirl. It is generally accompanied by violent rain, hail, and lightning; but whether the electricity manifested is cause or effect, is a disputed point. The cloud generally assumes the form of an inverted cone; and when it is over water, a whirling column of spray rises to meet it.

Even in the region of *variable* winds, some degree of regularity is observable. The south-west and the north-east prevail alternately during the greater part of the year, and by their conflict Professor Dove of Berlin accounts for the intermediate winds. He shews that as these variable winds veer round the compass, they usually follow a certain course—namely, from east to west by south in the northern hemisphere, and from east to west by north in the southern hemisphere.

* Every gradation exists in the speed of winds, from the gentlest zephyr to the most violent hurricane. They have been classed by Smeaton, according to their rapidity and force, as follows:—

Velocity. Miles per Hour.	Force on One Square Foot, in Pounds Avoirdupois.	Appellation.
1	·005	Hardly perceptible.
4	·079	Gentle breeze.
5	·123	
10	·492	Pleasant brisk gale.
15	1·107	
20	1·968	Very brisk.
25	3·075	
30	4·429	High wind.
35	6·027	
40	7·873	Very high.
50	12·300	Storm.
60	17·715	Great storm.
80	31·490	Hurricane.
100	49·200	Violent hurricane.

The winds between north and east have generally the smallest amount of *vapour*. At the same time, from their being the coldest, their actual dryness, or the difference between their temperature and the dew-point, is often less than in other winds. The south winds have both the greatest amount of vapour and the greatest vacancy or dryness.

The *pressure* of the air, or the height of the barometer, varies during the different winds. The barometer generally falls during south-east and south winds; passes from falling to rising during south-west; rises with west, north-west, and north winds; and has its greatest rise with north-east winds. The rise of the barometer with a north-east wind is very commonly remarked. The mercurial column is usually at its lowest between south and south-west.

It is a general law, or invariable connection, between the amount of vapour and the pressure of the atmosphere or the height of the barometer, that they change in opposite directions. In summer, when the quantity of vapour is greatest, the pressure of the air is least; and in the winter-time, the vapour being least, the weight of the air is greatest. Even in the daily fluctuations of these two quantities, this opposition is perceivable.

The fall of *rain* will depend upon a variety of circumstances. On the sea-coasts, and in places visited by moist winds, in which the approach to saturation is highest, the falls of rain will be most frequent, and there will be a greater degree of cloudiness prevalent in the sky. In the interior of continents, where the dryness is great, or the dew-point generally much lower than the temperature, rain will be less frequent, and the sky will be more transparent. In England and the west of France, there are, on an average, 152 rainy days in the year; in the interior of France, 147; in the plains of Germany, 141; and in the interior of Siberia, only 60. In many parts of Africa, rain never falls; in Upper Egypt, it is very rarely known. On the west coast of Britain, it rains much more frequently than on the east, the reason being, that the westerly winds—from the Atlantic—are moist winds, and give forth the greatest quantity of moisture on the land upon which they first strike.

When the visible vapour from a hot spring, a boiling caldron, or a steam-engine, extends in a long train, it is a sign that the air is nearly saturated with moisture, and that rain may be expected. If the appearance occurs about two or three o'clock in the afternoon, it may be reckoned as certain that there will be rain, mists, or dews at nightfall.

In extreme frosts, there can never be great falls of snow, the whole of the moisture contained in the air being too small to afford a copious precipitation.

In *predicting* weather by consulting instruments, it would be necessary to use the hygrometer along with the barometer and the thermometer. There are many exceptions to the common notion, that a high barometer indicates fine weather, and a low barometer the contrary. But even the barometer alone would be more certain if the following points were attended to—namely, in the *first* place, the actual height of the mercury; *secondly*, whether it is rising or falling; *thirdly*, the rate of rise and fall; and *fourthly*, whether the rise or fall has been of long duration. A slow rise continued for some days gives promise of settled weather; a steady and long-continued fall indicates that a tract of unsettled and stormy weather may be expected. There are also certain hours of the day which ought to be preferred for making the observations. For three observations daily, the proper times are—nine A.M. (a maximum height), twelve noon (a mean height), and three P.M. (a minimum height); when convenient, a fourth should be added—namely, three A.M. For two observations daily, nine o'clock morning and evening are the best hours; for one daily, noon is preferable.

These are the hours best suited for taking observations which are to be kept on record, and also for consulting the instrument to prognosticate the weather. If the column rise between nine A.M. and three P.M., it indicates fine weather; if it fall from three P.M. to nine P.M., rain may be expected. These rises and falls are contrary to its regular daily course, and therefore indicate considerable changes in the pressure of the air.

A sudden and great fall of the barometer is the sure forerunner of a violent storm. It shews that a great displacement or vacancy has occurred in the air over the place, and that a great inward rush will occur to make it good. A sudden rise would indicate an accumulation of air, which would cause an outflow in all directions, and would be also felt as a storm somewhere. A slow rise or fall shews that the influence comes from a great distance, or is owing to a permanent cause; hence, whatever the consequence may be, it will probably last for some time. A high barometer is a security against vehement influxes of air on any side, and therefore against the carrying in of moisture; hence it prognosticates dry and clear weather.

The hygrometer is very valuable in predicting weather; for as the quantity of vapour in the air increases or declines, so does the probability of the occurrence of rain. The hours already stated for the observation of the barometer are also well adapted for the hygrometer, with the view either of keeping a register or of ascertaining the course of the weather. The average pressure of the vapour for the day should be calculated by taking a mean between the dew-point at three P.M. and the lowest temperature of the sheltered thermometer at night.

By examining the barometer along with the hygrometer the prediction of weather is made much more certain. A fall of the barometer, accompanied with a rise in the dew-point, is an infallible indication that the entire mass of the air is becoming imbued with moisture; and a copious fall of rain may be looked for. If the fall of the barometer take place when the dew-point is low, we may conclude that the expansion that has occasioned the fall has taken place at a distant point, and wind without rain will be the result. When the temperature of the air sinks to the dew-point, with a high barometer, the effect is probably transitory, and produced by a local depression of temperature.

The Moon and the Weather.—The belief is almost universal, that the weather is influenced by the phases of the moon. A *change* of the weather, either from foul to fair, or from fair to foul, may be specially looked for, it is thought, at the times of new and full moon, or even at the quarters, though these last are not considered so influential. This belief is found to be altogether without foundation. Accurate observations, made with the express purpose, and extended over long periods, shew that there is not the slightest correspondence between the two sets of phenomena.

CLIMATES.

Isothermal Lines—Zones of Distinct Vegetation—Insular and Continental Climatology—Climate of London.

The climate of a place depends on its distance from the equator, its height above the sea-level, its position in reference to oceans, seas, and continents, the form of its surface, and the character of its soil. The points to be stated in reference to climate are, the mean temperature, the extreme winter and summer temperatures, the range of temperature daily, and from day to day, the humidity, the total fall of rain, the frequency of the falls, the relation of the amount fallen to the ordinary amount of vapour in the air, the prevailing winds, and the degree of variability of the weather. In general, the southern hemisphere of the globe is colder than the northern.

Humboldt divided each of the two hemispheres into seven belts or zones of climate, by supposing lines to be drawn round and round the globe, somewhat like parallels of latitude, each line running through all places whose *mean temperature* is the same. These are called *isothermal lines;* and as vegetation depends on warmth, they serve to distinguish the zones of distinct vegetation.*

Next the equator is the *equatorial* zone, or the *spice* climate, bounded by the line passing through places of 78° of mean temperature, which line lies nearly at 20° of latitude. The finest spices and the hardest woods thrive in this region. The second zone is the *tropical* climate, and is bounded by the line of 68°, and includes the climate of the sugar-cane and coffee-tree. In North America it is 31° from the equator; in Europe, the Mediterranean, Asia Minor, and Syria, it extends to 37° latitude; in Persia, to 31°. Here all the species of the palm-tree are in great perfection; the orange, lemon, and citron are of the most delicious flavour; and Indian corn, rice, cotton, tobacco, indigo, dye-woods, and drugs, are also among the productions. The third or *warm* climate extends to the line of 59°, the boundary of the olive and fig. In America it extends to latitude 36°; in Europe, to latitude 44°; in the west of Asia it extends to 40°; and in the central high regions, to 35°. This zone yields the olive, fig, almonds, peaches, apricots, the mulberry for feeding the silk-worm, the vine, yielding the choicest wines, the cork-tree, drugs, barilla, dried fruits, &c. The fourth or *temperate* climate coincides with the line of 50°, mean temperature, and is the limit of the wine-grape. In the middle of Europe it extends to latitude 50°, on the coast, to 52°; in England and Ireland, to 53°; in America, on the east coast, to 43°, and on the western coast, to about 50°; and in Asia it is as low as 40° latitude. It is the climate of grain, of the oak, beech, maple, and other valuable timbers; also of plums, cherries, apples, and pears. The fifth or *cold* climate terminates at the line of 41° of temperature, which is the northern boundary of the oak and of wheat: it yields the pine and fir, oats, barley, rye, apples, pears, nuts, gooseberries, and strawberries. The sixth or *frozen* climate is bounded by the line of 32°, or freezing; it extends in Lapland to 66° latitude; and to Table Bay, Labrador, at 54°. It contains little vegetation; its chief productions are animal products, such as whalebone, train-oil, and furs. Beyond this is the seventh or *polar* climate, which extends to the region of perpetual snows, where all vegetation ends: it yields only a few stunted shrubs, lichens, and mosses.

In ascending a mountain, we find a gradual diminution of temperature, analogous to the transition from the equator to the poles; and the same succession in the classes of vegetable life. On the sides of Tenerife, Humboldt observed the vegetation of nearly all the climates of the world. In temperate latitudes, though the variety of vegetation be less, similar phenomena present themselves. 'We may begin the ascent of the Alps, for instance, in the midst of warm vineyards, and pass through a succession of oaks, sweet chestnuts, and beeches, till we gain the elevation of the more hardy pines and stunted birches, and tread on pastures fringed by borders of perpetual snow. At the elevation of 1950 feet, the vine disappears; and at 1000 feet higher, the sweet chestnuts cease to thrive; 1000 feet further, and the oak is unable to maintain itself; the birch ceases to grow at an elevation of 4680, and the spruce-fir at the height of 5900 feet, beyond which no tree appears. The rhododendron ferrugineum then covers immense tracts to the height of 7800 feet, and the herbaceous willow creeps 200 or 300 feet higher, accompanied by a few saxifrages, gentians, and grasses, while lichens and mosses struggle up to the imperishable barrier of eternal snow.'

* Places which have the same mean annual temperature vary considerably in their mean summer and winter temperature; hence *isochimenal* lines, or lines of equal winter temperature, and *isotheral* lines, or those which shew equal summer over points upon different isothermal curves.

But the mean temperature is not the only circumstance which determines the vegetation of a place. The boundary of some plants depends on the lowest temperature of winter; and the advantageous cultivation of most plants is ruled by the greatest summer heat, as in the case of the vine, the olive, and maize or Indian corn. Barley is said to ripen wherever the mean temperature of ninety consecutive days rises to 48°. It is highly improbable, and in opposition to all evidence, that the mean temperature of any place on the globe has been changed within the periods known to history.

Between the tropics, the year is divided into the wet and the dry seasons. The wet or rainy season is the summer, or the time of the sun's most direct action; in *north* latitudes it extends from April to October. The division of the year into four seasons is known only in the temperate zones, or between 40° and 60° of latitude.

The western coasts of continents beyond the tropics have a much higher temperature than the eastern coasts, arising, partly at least, from the heat evolved in the condensation of vapour from the prevailing westerly winds.

Next to the distinction of climates into hot and cold, is the difference between *insular* and *continental* situations. Insular climates are kept temperate by the sea; they do not experience the extremes of heat and cold that are felt in the interior of continents. Thus if we compare Nova Zembla with Fort Franklin, which have nearly the same mean temperature, we shall find in the extremes of each the indication of its position:

	Nova Zembla.	Fort Franklin.
Mean temperature, . . .	16°·	17°·6
Mean of three summer months,	36 ·5	50 ·4
" " winter " ,	—3 ·	—17 ·8
Extreme heat, ...	49 ·	80 ·
" cold, ...	—53	—58
Range of heat and cold, . .	102	138

Both the vegetation and the feelings of human beings will be very different in these climates. The high summer heat of the one will favour the growth of many plants, and give a tone of warmth and cheerfulness; the miserable cold mediocrity and monotony of the other will be barren and disheartening.

The British Islands are situated so as to experience almost all the circumstances that can render a climate irregular. Standing nearly in the centre of the temperate zone, where the range of temperature is very great, they are subject on one side to the impressions made on the atmosphere by the greatest continent of the world, and on the other side to the influences of the Atlantic Ocean. The Gulf Stream (see Physical Geography) is believed to have considerable influence in mitigating the rigour of winter in the British Islands and the west of Europe generally.

On the average of ten years, the westerly winds are to the easterly, in Great Britain, as 225 to 140; and the northerly to the southerly as 192 to 173. Of east winds, the northerly exceed the southerly in the proportion of about 74 to 54; thus the south-east, which is the most irregular point of all, has but a small proportion. The south-west are to the south-east as 104 to 54.

Within the boundaries of Great Britain there is a considerable variety of climate. The character of each place can be ascertained only by a long series of well-conducted instrumental observations; and few places have as yet received this degree of attention. Hitherto London has been the place most carefully observed.

The mean pressure of the air at London, as deduced from twenty years' observations by Mr Howard, is 29·8655, or very nearly $29\frac{9}{10}$ inches. The mean temperature derived from the daily extremes is $49\frac{1}{2}$°. The mean dew-point is $44\frac{1}{2}$°, giving a mean dryness of 5°, which for these numbers corresponds to a vacancy or dryness of ·058, or nearly $\frac{1}{17}$th of an inch. The average quantity of rain is 22·199 inches annually, and the amount of evaporation is calculated at 23·974 inches—that is, considerably greater than the entire amount received by precipitation.

The range of the barometer is from 30·82 inches to 28·12 inches; the maximum temperature of the air is 90°; the minimum 11°; the range of the dew-point is from 70° to 11°. The highest temperature of the sun's rays is 154°, and the lowest temperature on the surface of the earth 5°. The greatest interval between the temperature and the dew-point is 29°.

ELECTRICITY OF THE ATMOSPHERE.

Thunder and Lightning—Aurora Borealis.

The electric phenomena of the atmosphere possess great interest, but are as yet imperfectly understood (see Electricity). The condensation of vapour is thought to be the most productive source of the electricity of the atmosphere. The excitement is much oftener positive than negative. The discharges of the excitement are well known under the terms *thunder* and *lightning*, and they generally accompany storms and hurricanes, but rather as effects than causes. According to Mr Crosse, a thunder-cloud consists of zones alternately positive and negative; and different strata of serene air are often in different relative electric states. Such a state of things makes the whole subject of atmospheric electricity exceedingly complicated.

The *aurora borealis*, one of the most beautiful of meteoric phenomena, is now ascertained to be connected with the *magnetism* of the earth. Faraday has shewn that magnetic forces can produce light; and the appearance of the aurora is always preceded by a disturbance of the earth's magnetism, as shewn by the vibrations of the magnetic needle. The polar light is a magnetic discharge—the termination of a magnetic storm—just as a flash of lightning indicates the restoration of the disturbed electrical equilibrium. The rays of the aurora appear to converge towards a point in the vault of the heavens corresponding to the inclination of the magnetic needle. The formation of fleecy, cirrus clouds is always more or less connected with the appearance of the aurora. These clouds may often be observed even by day arranged similarly to the rays of the polar light; and they are then found to disturb the course of the needle in a similar manner.

LUMINOUS METEORS.

Rainbows—Halos—Parhelia—Coronæ, &c.

The various luminous appearances of the heavens, apart from the ordinary phenomena of sun, moon, and star light, are usually treated of under Meteorology.

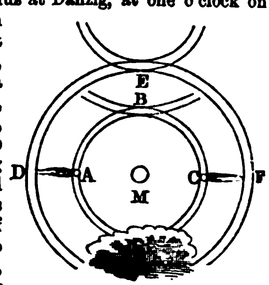
If there were no atmosphere, the heavens would be intensely black at all times, and the heavenly bodies would be brilliant lights set in the deepest shadow. The air, however, diffuses and reflects the sun's light, so that a portion of it is received from every part of the sky, causing a general illumination of the entire vault of heaven. This reflected light ought to be always of a whitish character, like the light of the sun itself made very much fainter. But we find that the sky, when clear, has a strong blue tinge, which deepens into black as we ascend to great heights. The blueness arises from the peculiar action of the atmosphere upon light. If any white beam pass through a great thickness of air, the red will be transmitted most readily, and the blue resisted and reflected; hence the reflected rays of the sun's light have a bluish tinge instead of being pure white. The reddish character of light transmitted very obliquely through a great thickness of atmosphere, is exemplified in the ruddy illumination of the sky and the clouds at sunset.

The *rainbow* is owing to a complicated reflection and decomposition of the rays of the sun in passing through drops of rain. It appears when the sun is unclouded, and rain is falling in the opposite quarter of the heavens.

The mode of its formation is more particularly explained under OPTICS.

Halos are coloured rings which surround the sun at considerable distances from his body. Two of them may be seen at once, the one about double the distance of the other; and sometimes a third, at twice the distance of the second, and about 90° or a quarter of a circle from the sun. The smaller circles are generally coloured, the red being innermost. They are supposed to rise from the action of the icy particles in the upper air upon the rays of light. These particles naturally aggregate into needles or prisms of three or six sides, and the refraction of the light through them would account for the colours of the rings, and for the distances at which they stand from the sun. *Parhelia*, or mock-suns, and *paraselenæ*, or mock-moons, are supposed to be owing to reflection from the same icy particles.

In the annexed figure, a representation is given of a lunar halo seen by Hevelius at Danzig, at one o'clock on the morning of the 30th March 1660. When first perceived, the moon, M, was surrounded by a complete whitish circle, ABC, 45° in diameter, while at A and C were mock-suns, displaying *various colours*, and shooting out at intervals very long streams of whitish light. At two o'clock, the larger circle, DEF, was seen reaching down to the horizon, having a diameter of 90°. The tops of both circles were *touched* by *coloured arches*, like inverted rainbows, the *red* tint being *next to the moon*. The arch B was part of a circle equal in size to DEF, while that at E was a portion of a circle of the same magnitude as ABC. Such is the general structure of halos: the identity existing in the magnitude and arrangement of their several parts, clearly shews that they must originate in certain fixed laws; but what those laws are has not yet been fully determined.



The true halos are to be distinguished from the *coronæ*, or *glories*, that surround the sun or moon when a thin cloud passes over them. These depend on a different optical principle. When fine powder of any kind is interposed between the eye and a luminous object, rings of colours are formed, whose size depends on the dimensions of the powder. Visible vapour will produce this effect; and it also arises from the fine dust always held in suspension in the air of a room. Such rings can be observed round a candle-flame at any time, if we stand at a proper distance from the light; and by the agitation of the dust, they may be made still more visible. By calculation, Dr Young has shewn that rings 8° in diameter are produced by particles of powder, or drops whose diameter is $\frac{1}{3181}$ of an inch.

IGNEOUS METEORS.

Shooting-stars—Fire-balls—Meteoric stones—Aërolites.

Shooting-stars are observed during serene nights. A luminous point like a star bursts into view, shoots a certain way through space, and then disappears. Its brilliancy fades before it is extinguished. Sometimes it leaves a luminous train behind it; in other cases it gives forth sparks. These meteors have been noticed to occur in great numbers at once; and the interest of such appearances has been very much increased by the fact of their being in some measure periodical. On several years they have been found to occur in the month of November; from which circumstance they are sometimes called November meteors. They also occur with some degree of frequency in August. Shooting-stars and *fire-balls* break out occasionally at every period of the year.

When a fire-ball bursts, the fragments fall to the earth, and are called *meteoric stones*, or *aërolites*, from the Greek words *aër*, atmosphere, and *lithos*, a stone. Many of these stones have been procured and examined, and found to be quite unlike any mineral of terrestrial origin; hence the most likely theory of their derivation is, that they are fragments flying through space, under the influence of the same forces which sustain the planetary motions, and that they sometimes come within the sphere of the earth's attraction, so as to be drawn down to its surface. There is every reason to believe that the planets, satellites, and comets are not the only bodies which move round the sun, and lie within the solar system—they are merely the large conspicuous masses; while millions of others may exist, too small to be descried on ordinary occasions, and making themselves known only by falling upon the earth. Their illuminated appearance is supposed to be owing to their taking fire when they come in contact with the oxygen of our atmosphere. They themselves have evidently no oxygen atmosphere of their own, but are not improbably surrounded by some inflammable gas, the combustion of which forms the luminous train that they leave in their track. To account for the periodicity of the November meteors, it is imagined that a great number of them may move in a continuous ring or common orbit round the sun, so situated that the earth, in its annual course, brushes, as it were, with the outskirts of its atmosphere this ring of planetary fragments once a year. Some of them pass into the atmosphere, and go out again, without falling to the earth; shewing that the earth can only deflect them a certain way, and is not able to draw them completely down to the surface.

One of the most familiar of luminous meteors is the *ignis fatuus*, or 'Will o' the wisp,' which appears at night on marshy grounds, places of sepulture, or wherever putrefaction and decomposition are going on. The appearance is that of a small flickering light, straggling in an irregular manner at the height of one or two feet from the ground, and sometimes standing for a few moments over a particular spot. When approached or pursued, the lights are agitated by the motion of the air, and seem to elude investigation. The cause of this species of meteor is supposed to be an evolution of phosphoretted hydrogen gas, which, properly speaking, does not burn as a flame, but is only faintly phosphorescent.

Until recently, meteorological observations had been mostly casual and without any uniform plan; hence the vagueness and uncertainty that hang over so much of the subject. But since 1840, the earth has been covered with a net-work of meteorological observatories, maintained by the several European governments—Russia and England taking the lead—in which observations of a variety of physical phenomena are made on a concerted plan, determined on by savans in congress. In consequence also of a maritime congress held at Brussels in 1853, chiefly at the instigation of Lieutenant Maury of the United States, the chief maritime nations are taking means to render every ship, whether man-of-war or merchantman, a floating observatory, by furnishing captains with instruments and instructions how to record what they see. Observations of a more local kind are also being actively prosecuted in various quarters, with a view to the interests of agriculture. A recent writer in the *North British Review* is of opinion that 'had Hipparchus and Ptolemy made hourly observations, and had they been made also by their contemporaries and successors in different parts of the world, we might now have been predicting the weather with as much certainty as we do the planetary motions.' Without being quite so sanguine, it is not unreasonable to anticipate that, with the agents and apparatus now at work in this field, the next half-century may see light and order arising out of many things that now seem nothing but chaos.

PHYSICAL GEOGRAPHY.

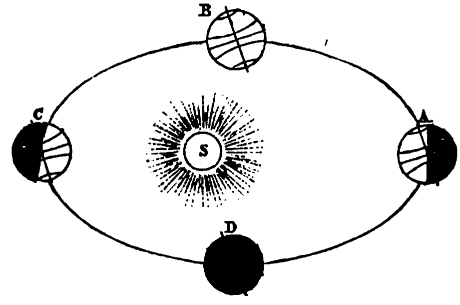
GEOGRAPHY—from *gé*, the earth, and *grapho*, I write—in its simple and literal signification, is that science which describes the superficial appearance and conditions of our globe. It naturally divides itself into two great branches—1. *Physical Geography*, which treats of the earth as a superficies composed of land and water; considers the position, extent, altitude, and general character of the former; and the position, extent, depth, currents, and other motions of the latter: in short, all that relates to the distribution of land and water, variations of surface, temperature and climate, and distribution of plants and animals as dependent thereon, are the legitimate objects of this species of geography. 2. *Political Geography*, which refers merely to the division of the earth's surface by man into territories, empires, kingdoms, and states, treats of their boundaries, the history of their occupation, their produce, commerce, population, laws, religion, and other topics which constitute the fundamental features of human polity. The latter of these branches will form the subject of several subsequent treatises; to an exposition of the former—dwelling more on principles than on mere descriptive details—we intend to devote the present number. Before doing so, however, it will be necessary to advert to the cosmical relations and constitution of our planet, as determined by astronomy, geology, chemistry, and meteorology.

GENERAL CONSTITUTION OF THE GLOBE.

Astronomy informs us that the earth we inhabit is one of a number of *planets* which revolve round the sun as a common centre, constituting what is usually denominated the SOLAR SYSTEM. These planets are situated at different distances from the central orb, and differ also in their magnitudes, their densities, and in their periods of revolution. They are nearly spherical in form, are opaque, have no light of their own, but merely reflect that of the sun; and all move from west to east in nearly circular orbits. Several of them serve in turn as centres for other bodies of revolution, which are known by the name of *satellites*—as the moon, for example, which is the satellite or attendant of the earth. Besides the planets and their satellites, there is a third and numerous class of bodies belonging to the solar system—namely, *comets*, which revolve round the sun in regular periods, but in orbits so elliptical, that in parts of their course they approach nearer to the great orb than any of the planets, and in others recede so far into the regions of space, as to be entirely beyond the reach of our most powerful telescopes. The *stars* belong to other systems of revolution, and have, so far as has yet been determined, no perceptible effect upon the conditions of our globe, though undoubtedly bearing, like everything in nature, a universal harmonious relationship.

The earth, as an individual planet, is situated at the distance of 95,173,000 miles from the sun; has a mean diameter of 7912 miles; performs a revolution round the sun in 365 days 5 hours 48 minutes and 49 seconds, which constitutes the space of time called a year; rotates on its own axis once in 24 hours—that is, in one day; and in these movements is attended by the moon, which is distant 237,000 miles, is 2160 miles in diameter, and which completes her synodic revolution in 29 days 12 hours and 44 minutes, or in one lunar month. We have spoken here of the *mean* diameter of the earth, because, upon accurate measurement, it has been found to be not a perfect sphere, but an *oblate spheroid*, whose greater diameter is 7925·648, and whose lesser is only 7899·170 miles. This gives a difference of 26·478 miles between the two diameters, or a flattening at each pole of about thirteen miles—a result that may be artificially illustrated by twirling with rapidity a ball of any yielding material, such as putty, round a spit thrust through it as an axis, when a bulging at the outer circumference will take place, causing the ball to lose its original spherical form. This bulging takes place through what is called the law of centrifugal force; and from what we know of this law, it is concluded that the earth was in a soft or yielding state at the time when it assumed its present form. Besides the bulk, revolutions, and configuration of our globe, science has also determined its *density* with considerable accuracy. By weighing the most prevalent rocks, it has been found that the solid crust composed of them is about two and a half times heavier than water; but from experiments made on the attraction of mountains of known bulk, compared with the attraction and bulk of the globe, and by other means, it has been inferred that the density of the whole mass is five or six times that of water: in other words, the earth, as at present constituted, is five or six times heavier than a globe of water of similar dimensions, and more than twice the weight of one composed of such rocky substances as those with which we are acquainted. In addition to what may be called its own proper material, the earth is surrounded by a gaseous envelope or atmosphere. This *atmosphere* or air is peculiar to, and inseparable from, our globe—it rotates with the solid mass upon its axis, and does not, as may at first be supposed, occupy the space in which the rest of the heavenly bodies revolve. Like all aëriform and liquid masses whose particles press upon each other equally in every direction, the portions or strata next the earth are more pressed upon than those in higher regions; and continuing this conception, a height must be arrived at where the air becomes so attenuated as to be inappreciable. Thus it has been determined that the atmosphere does not extend beyond forty-five miles from the mean level of the ocean.

From its planetary relations, as a part of the solar system, the earth derives its figure and motions, its light and heat, and consequently the changes of season, and the alternation of day and night; the phases of the moon, and the rising and falling of the tides; the vicissitudes of wind and weather, and all the varied results and phenomena that flow therefrom. Thus,



while its figure is preserved by the laws of centripetal and centrifugal force, its motions are determined and influenced by the attraction and gravitation of the sun

and other planets. From its situation with respect to the sun, it necessarily follows that only one-half of its surface can be exposed at a time to the light and heat diffused from that orb, thereby causing day in the one part, and night in the other. The *seasons*, again, are caused chiefly by the fact, that in performing its path round the sun, the earth preserves its axis in a slanting or oblique position, to the extent of 23° 28′ from the perpendicular. A glance at the figure shews how this obliquity makes the several parts of the earth's surface receive different amounts of light and heat in different parts of its orbit; as has been more particularly explained in ASTRONOMY. In like manner, did our limits allow, might be explained the phases and influences of the moon, and the fluctuations of heat and cold, with their myriad consequences to animal and vegetable existence. So indissolubly connected is the whole scheme of creation, that not a shower that falls, not a particle of sand that crumbles away from its parent rock, or a spikelet of grass that turns sunward, but may be traced to the one great law which originally set the sun and its attendant orbs in motion.

The solar system, however, vast as it seems, is but a unit in space, which is peopled with other systems and orbs circling and encircling beyond the bounds of human conception. What we term *fixed stars* are but suns and centres of revolution; and the solar system, as a whole, may revolve in space round some vast centre, just as its individual planets have their motions round the sun. From such a revolution may arise cycles of heat or cold, life or death, exuberance of certain living forms, and annihilation of others—cycles which meet with a faint analogy in the recurrences of our summers and winters. We know nothing of the constitution of what we call space, or of the ethereal essences which pervade it; and it is not unlikely that as the solar system passes through successive regions, causes may operate on a scale sufficiently vast to impress new conditions upon the whole of the planets which constitute that system. But, whether our earth be or be not affected by causes so remote and universal, we know for certain that its history, from the beginning of time, has been one of incessant mutation and progress.

The materials of which the earth is composed present a history not less curious than that of its planetary relations. Superficially speaking, the globe consists of land and water; the water occupying the extreme depressions of the land, and this land composed of solid or rocky materials. That the same kind of rocks which appear at the surface do not constitute the interior or central portions, we have evidence from the mean density of the earth; for were the law of gravitation to exert itself uniformly towards the centre, the lightest substance at the surface would be so compressed at the depth of a few hundred miles, as to give to the whole a greater density than astronomical calculations will allow. The interior, therefore, must consist of very different material from the exterior, and this has led geologists to speak of the earth's *crust*, whose composition we know, in contradistinction to the central portion, concerning which we can only form conjectures. This crust, or external shell of solid matter, consists of rocks, differing not only in their appearance and arrangement, but in their mineral and chemical characters; some being compact and crystalline, as marble, others soft and dull, as chalk; some lying in layers or strata, others occurring in huge irregular masses; while, mineralogically and chemically speaking, we have such rocks as granite, quartz, slate, lime, coal, rock-salt, chalk, and clay. But the crust so composed, compact and solid as it may seem, is far from being permanent and stable; in other words, the dry land which now appears, with all its irregularities of hill and valley, plain and ravine, lake and river, is not the dry land which existed many thousands of years ago. Strictly speaking, indeed, the aspect of the globe is ever changing. Here the sea encroaches on the land, there the débris borne down by rivers silts up bays and estuaries; here earthquakes sink, and volcanoes elevate the surface; lakes are dried up, and rivers change their course; and, greater than all of these, vast regions gradually subside, and are covered by the ocean, while others as gradually emerge from the waters, and become dry land. All these changes, past and present, form the subject of geological consideration.

Geology, in its aim to decipher the physical history of our globe, has determined that all the known rocks may be ranked under two great sections—the *stratified* and the *unstratified*. The former appear in layers or beds, and have evidently been deposited in water, hence said to be *aqueous* or *sedimentary;* the latter appear in vast irregular masses, generally disrupting the stratified

rocks, and have all the appearance of having been formed like the lavas of the present day; hence they are called *igneous* or *volcanic*. Of the sedimentary rocks, sandstone, limestone, slate, and coal may be taken as illustrative examples; of the igneous, granite, basalt, greenstone, and lava are the most familiar. As at present, so in all time past, the surface of the earth has been subjected to atmospheric, aqueous, and other influences, the effects of which are to wear down the exposed material; and this, borne away by floods and rivers, is deposited in the ocean, where, consolidated by pressure, heat, and chemical agency, it forms new strata of rocks, which in time are brought to the surface by volcanic and other elevatory forces. Thus, then, one set of agencies degrade, and another reconstruct and elevate; and in proportion as either of these preponderate, so will any portion of the earth be low and level, or high and precipitous. Such, then, is the origin of the stratified and unstratified rocks—the one but the reconsolidated matter of pre-existing rocks, which have been worn and battered down by rains, frosts, waves, and rivers; the other the cooled and hardened material sent forth from the interior of the earth by volcanic agency. But while rivers and floods bear down mud, sand, and the like, they also carry such vegetable and animal remains as lie in their course; and in this manner plants and animals are entombed in the newly formed layers or strata. As at present, so in former eras, such remains have been enclosed in the stratified rocks, where, subjected to certain chemical agencies, they have become petrified, and are thus preserved as records of the former Flora and Fauna which peopled the globe. Geologists have, accordingly, found that the earth has not always been occupied by the same kinds of plants and animals that now exist; but that different eras in its onward history have had very different Flora and Fauna, and that at present not one perhaps of its former genera is in existence.

Aided by the mineral composition of the rocks themselves, and by these fossil organisms which are found in them, geologists have arranged the strata composing the accessible crust into *formations;* that is, into series of strata which seem to have been deposited under the same terrestrial conditions. Thus the *primary* formation includes the hard crystalline and slaty strata, as gneiss, mica-schist, clay-slate, &c., in none of which organic remains have yet been found, and whose material has evidently been derived from the granitic rocks on which they rest as a basis or foundation. Next in succession above the primary are the *transition* rocks, so called from their containing remains of vegetable and animal life, and as indicating the transition of the globe from an unpeopled to a peopled condition. This formation consists of hard quartzose sandstone, certain indurated

slates and limestones, and of the marls, shales, and sandstones known by the name of 'the old red sandstone.' Its fossils consist chiefly of infusory animalcules; corals, shell-fish, and fishes, and of sea-weeds and a few lowly organised terrestrial vegetables. Then comes the *secondary* formation, subdivided into the older and younger; the former comprehending the mountain limestone, coal, bituminous shales, ironstone, clays, and soft thick-bedded sandstones; and the latter the new red sandstone, magnesian limestone, and those calcareous groups known as the lias, oolite, and chalk. In the older secondary, corals, shell-fish, and fishes are exceedingly prevalent; and vegetation during that era was so prolific as to furnish the material of which coal is formed: in the younger secondary, vegetation is less abundant, but shell-fish, fishes, and strange gigantic fish-like reptiles are everywhere to be found, and of forms not now in existence. Next in ascending order lie the beds of the *tertiary* formation, consisting of clays, marls, soft sandstones, limestones, and gypsum; and in which the remains of birds, mammalia, and vegetables somewhat like existing genera are for the first time discovered. Above all these formations are scattered the clays, gravels, sands, peat-mosses, and marls which constitute the *superficial accumulations* of the current era; and in these are found the remains of existing races of plants and animals, some species of which, however, have already become extinct in several regions. Intermingled with these formations—now throwing them up in hills or depressing them in valleys; now overlying them in mountain masses, or breaking and contorting them in the form of veins and dikes—are the igneous rocks, the granites, basalts, and traps of past ages, and the lavas of the present era.

All this succession and accumulation of strata, this appearance and disappearance of different races of plants and animals, indicate the lapse of innumerable ages—ages through which the earth has progressed from phase after phase to that which it now presents. What a strange and checkered history! Nor does it yet present, in any of its physical relations, a single aspect of rest or stability. The conditions of its constitution forbid this; and while we write, rocks are wearing down, rivers are laden with débris, new strata are being deposited, volcanoes are elevating, earthquakes are depressing, and land and sea are gradually changing places, as they have done in all times bygone. All the stratified rocks which we have enumerated have been deposited in the ocean, in estuaries, or in fresh-water lakes; and could we accurately map out the sites and limits of these deposits, we should find that at no two periods in its history has our planet presented the same distribution of land and water. All that we know for certain is, that, from the earliest dawn of the stratified formations up to the current moment, there have been sea and dry land, rains, springs, rivers, and all those degrading and transporting agents which are in incessant operation around us. What the altitude and irregularities of this dry land, what the depth and constitution of this ocean, we may never ascertain. We know, however, that the same rocky material has undergone successive rounds of disintegration and reformation; that this material is essentially made up of silicious, calcareous, argillaceous, bituminous, metallic, and saline constituents, and that these constituents, as well as those of plants and animals, are compounded of about sixty elementary substances; of which, at the ordinary pressure and temperature of the atmosphere, five are *gaseous*, and the rest mostly solid, by far the greater number—at least forty-two—being metals. (See CHEMISTRY.)

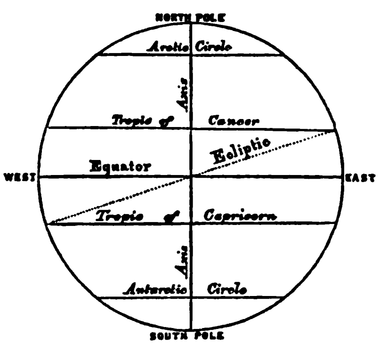
Of the constitution of the ocean, or watery portion of the earth's superficies, chemical research affords us equally accurate data. When pure, water is composed of 1 hydrogen and 8 oxygen by weight, or of 2 hydrogen and 1 oxygen by volume. In motion, however, water is generally found to contain many impurities—such as clay, sand, animal and vegetable matter, &c.—which, if left at rest, by their own weight soon fall to the bottom. Such substances are said to be *mechanically suspended*, and when deposited at the bottom, form sediment. Besides impurities of this description, water may contain matter which will not fall down, and which is said to be held in *chemical solution*. The saline matter in sea-water amounts to about 3½ per cent. of its weight, or nearly half an ounce to the pound. It consists chiefly of common salt, sulphate of soda, chloride of lime, and of magnesia. The saltness of the sea, however, is not quite uniform. In general, it is greater in the trade-wind regions than in extra-tropical; or wherever evaporation exceeds precipitation. A rainless sea, like the Red Sea, is considerably salter than the ocean generally; the Baltic again, which receives a great many rivers, contains only half as much salt as the Atlantic. It is often found that while a comparatively fresh current is flowing one way on the surface, a salter undercurrent is setting in the opposite direction. A knowledge of the constitution of the ocean is necessary to the explanation of numerous facts in geology and biology. The saline constituents must influence more or less all chemical changes, rock deposits, and animal and vegetable life, which take place in the ocean. From these constituents, mollusks and coral animalcules obtain the material of which shell-beds and coral-reefs are constructed; and by this same constitution, marine plants and animals are made to assume external characters which distinguish them from the inhabitants of fresh waters.

The *atmosphere*, the next great constituent of the globe, plays an equally important part in the organic and inorganic economy. Pressing with a weight of about fifteen pounds upon every square inch at the ordinary sea-level, and diminishing in density upwards in geometrical progression, it is evident that animals and plants fitted to live at small elevations will die if removed to great heights—a circumstance corroborated by the fact, that travellers experience difficulty in respiration on very high mountains, and that blood has been known to start from their ears and other tender parts under the diminished pressure. Calculating from data afforded by its density, a limit has been assigned to the atmosphere at the altitude of forty-five miles—or about forty miles above the top of the highest mountains. Notwithstanding its transparency, the air intercepts and reflects the sun's rays, multiplies and propagates them by an infinity of repercussions; and were it not for this property, objects would never be illuminated unless exposed to the direct light of the sun. It is also the recipient and retainer of the solar heat reflected from the earth; and were it not so constituted, the solar rays would be returned to space, and an excessive cold continually prevail. Besides, according to the general physical law, that the capacity of gases for heat increases with their rarity, bodies placed in the upper regions of the atmosphere have their heat so rapidly abstracted, that they are ever beneath the freezing-point; hence the perpetual snows and glaciers of the higher mountains. Chemically speaking, the atmosphere is a gaseous admixture—every hundred parts of which are composed of 79 nitrogen and 21 oxygen—with about one part in 2000 of carbonic acid. In addition to these, which are its permanent constituents, there are always traces of ammonia and a certain amount of aqueous vapour, amounting from 1 to 1·8 per cent.; in certain localities, also minute quantities of other ingredients are to be occasionally detected. The atmosphere may therefore be regarded as the laboratory in which clouds, rain, snow, and other vapours are formed—the medium through which the light and heat of the sun are diffused and equalised—an element without which animal and vegetable life could not exist, for both incessantly inhale and exhale its elements; and an agent indispensable to those innumerable physical operations which constitute the progressive history of our planet.

Thus assisted by the determinations of astronomy, geology, chemistry, and meteorology, as regards the general constitution of the globe, physical geography proceeds to describe and account for its superficial appearance and conditions, and those, again, as influencing the life and distribution of the plants and animals by which it is peopled. Before entering, however, upon these interesting but complicated details, it will be necessary to explain the principal terms and technicalities usually employed by geographers.

GEOGRAPHICAL TERMS.

The direction from which the earth moves in its daily rotation is called the *West;* that towards which it moves, the *East;* the point which is on the right hand of one standing with his back to the east is called the *North;* that on the left hand, the *South.* The imaginary line on which the earth turns is called the *Axis;* its termination towards the north is known as the *North Pole;* that towards the south, the *South Pole.* The early cultivators of geography, dwelling on a part of the earth nearer the north than the south pole, supposed the former to be uppermost, though, in reality, such ideas as upper and under do not belong to astronomy; and it is for this reason that in globes and maps the northern part is always placed at the top, the east being towards the right, and the west towards the left hand, with the south at the bottom. Exactly between the two poles, and consequently dividing the earth into two equal portions, is a line called the *Equator;* all



north and south of which are respectively called Northern and Southern Hemispheres or Half-spheres. In the same way, an encircling line, at right angles to the equator, divides it into Eastern and Western Hemispheres. The circuit of the earth, both in its girth between east and west, and between north and south, is divided into 360 parts, called *degrees,* each degree being equal to about 69½ British miles. At the distance of 23½ of these degrees from the equator, in both directions, are two parallel lines called the *Tropics,* in reference to the sun's declination; known respectively as that of *Cancer* and *Capricorn,* from these constellations being situated in a corresponding part of the sky. At the same distance from each pole is a parallel line—that on the north being styled the *Arctic,* and that on the south, the *Antarctic Circle.* The spaces between the tropics are called *Torrid Zones,* because the sun, being always vertical in some part of that space, produces a greater degree of heat than is felt in regions where his rays strike more obliquely. The spaces between the tropics and the Arctic and Antarctic Circles are styled the *Temperate,* and the spaces within these latter circles, the *Frigid Zones.* Lastly, a line, which cuts the equator obliquely, touching upon opposite points of the tropics, is called the *Ecliptic.* The points where the ecliptic cuts the equator are termed *Equinoctial Points* or *Nodes;* and when the sun is in that part of his course, the day and night are of equal length. These equinoxes of course occur twice during the year—namely, the 21st March and 21st September. The ecliptic and equator are sometimes called *Greater Circles,* because they encircle the earth at the thickest parts; the others above enumerated are all *Lesser Circles.* A series of lines drawn from pole to pole over the earth's surface, and cutting the equator at right angles, are called *Meridians,* from the Latin *meridies,* mid-day. Every place upon the earth is supposed to have one of these passing through it, although it is usual to describe only twenty-four upon the surface of the terrestrial globe. When any of these is opposite the sun, it is then mid-day, or twelve o'clock, with all the places situated on that meridian; and consequently midnight with those on the opposite meridian, on the other side of the earth. Thus, when it is twelve o'clock at noon in any particular part in Britain, it will be twelve o'clock at midnight in a corresponding part on the opposite side of the globe—that is, with our *Antipodes*—near New South Wales; and the intermediate hours, sooner or later, will all lie in the countries between these two points, exactly according to their position or degrees of longitude.

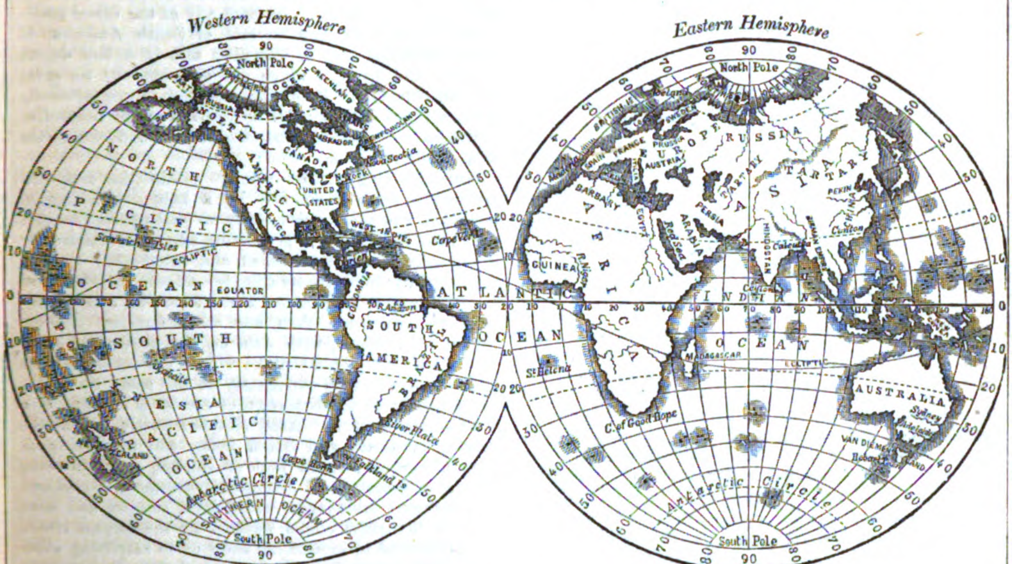
The exact situation of a place upon the earth, or its latitude and longitude, is determined by means of these circles. They are all divided, as already stated, into 360 parts, which parts are called *degrees;* these degrees again into 60 equal parts, called *minutes;* the minute into 60 others, called *seconds;* and so on. They are usually indicated by certain signs—thus, 8° 5′ 7″, is 8 degrees 5 minutes 7 seconds. The *latitude* of a place is its distance measured in that manner from the equator. If it lies north of that line, it is in north latitude; if south of it, in south latitude. There being only 360 degrees in the circumference of the earth, and the distance from the equator to either of the poles being only a fourth part of it, a place can never have more than 90 degrees of north or south latitude. The *longitude* of a place is the distance of its meridian from another, which is called the *first meridian.* The first meridian is quite arbitrary, and it is a matter of indifference through what point we draw it, provided it be settled and well known which one we adopt, so as to prevent mistakes. In Germany, the island of Ferro is generally adopted; in France, the observatory of Paris; and in England, that of Greenwich. Longitude is reckoned either east or west of the first meridian; and 180 is therefore the utmost degree of longitude. Some geographers, however, reckon longitude all the way round the globe. From the meridians all tending to a point at either pole, the degrees of longitude necessarily decrease as we approach these points from the equator.

Besides these terms and technicalities, which refer to the earth as a whole, there are others employed to designate its separate portions of land and water. Thus of the land, a *continent* is any vast region uninterrupted by seas; an *island,* any smaller portion surrounded by water; a *peninsula,* a portion nearly surrounded by water; an *isthmus,* the narrow neck which connects a peninsula with the mainland; a *cape, promontory,* or *headland,* a point of land jutting out into the sea. As to the water, a large uninterrupted extent of sea is called an *ocean;* smaller portions are known as *seas;* a bend of the sea into the land, a *bay;* a deeper indentation, a *gulf;* a narrow strip of sea, a *strait* or *channel;* and where the sea stretches inland to receive the waters of some large river, it is termed a *firth* or *estuary.* Referring to the surface of the land, without any reference to water, extensive flats are known as *plains, steppes, pampas,* &c.; smaller ones as *valleys, straths,* and *dales;* elevated land is spoken of as rising into *hills,* or, still higher, into *mountains;* and level elevated tracts are known by the name of *table-lands* or *plateaux.* Running water makes its appearance in *springs,* many of which conjoined form *streams,* and streams *rivers;* and where these become stagnant, and spread out into inland sheets, they take the name of

lakes. The bounding-line of land and water is termed the *shore*, and the land bordering on the sea in any place is generally spoken of as the *coast* or *sea-board.*

DISTRIBUTION OF LAND AND WATER.

To exhibit the earth's surface at one view, it is usual to map it into two halves or hemispheres—the Eastern comprehending the one great continent of the *Old* World, or that known to the ancients; and the Western, or *New* World, discovered and explored since the close of the fifteenth century. To these, modern geographers add a third—namely, *Oceania*, or the Maritime World, partly situated in both hemispheres, and comprising Australia and the vast groups of islands which stud the Pacific Ocean. It will be seen at one glance that the sea and land are very unequally distributed—that they preserve no regularity of outline or form—and that either is placed indifferently as to position, on the



earth's surface. Many fanciful conjectures have been offered to account for the configuration of the existing continents, but none of them seem to have any foundation in fact. The elevating and depressing causes mentioned under the head of GEOLOGY, are too violent and capricious to leave anything like regularity in their results, while it is a matter of indifference as to the planetary relations and equilibrium of the globe what portion of its surface be land or water. And yet, seeing that everything in nature is regulated with such order and harmony, there may be, though beyond our present means of detection, a progression as to the time and manner in which the various portions of the solid crust shall be elevated into dry land, or submerged beneath the ocean. It has been already stated, on geological authority, that the land and water have frequently changed places—and this changing implies vast revolutions in the kind and amount of the vegetables and animals which people the earth. Did the greater portion of the dry land exist between the tropics, for example, the Fauna and Flora of the world would be essentially different from what obtains at present, and still more so from that which could flourish were that land distributed chiefly in the polar regions. The distribution of land and water, therefore, though unimportant as regards the physical relations of the globe, is all-essential to the character of its life and humanity.

Though we are thus unable to account for the present relative arrangement of sea and land, there is one determining principle sufficiently clear—namely, that so long as the same quantity of water remains on the globe, a fixed amount of space will be required to contain it. If the difference between the elevations and depressions of the solid crust be small—in other words, if the hollows in which lakes and seas are spread out be shallow—their waters must extend over a greater space; and if these hollows be deep, the waters will occupy less extensive areas. The operation of this principle should be borne in mind; for if the inequalities of the land were generally less, the waters would occupy larger spaces, and this more extended area of shallow water would act in various ways. It would render the climate more genial and uniform; and, extending a greater surface to the evaporating power of the sun, rains and atmospheric moisture would be more prevalent. These, again, would influence the amount and kind of animal and vegetable life on dry land; while the shallow waters themselves would be more productive of life—it being a well-known fact that marine plants and animals flourish only at limited depths. Of terraqueous distribution at any former period of the world, we can only infer from the appearances which the surface and rocky strata present; but of the present distribution we have pretty accurate information, with the exception of those inhospitable regions surrounding either pole.

The proportion of dry land to water, as at present known, is about one to three—that is, two-thirds of the whole surface of the globe may be assigned to water. Estimating the entire superficies to contain 198,943,750 square miles, nearly 147,000,000 are occupied by water, and only 51,000,000 by dry land. Others, reckoning the entire area of the globe at 197,000,000 square miles, assign seven-tenths as the proportion of space occupied by the ocean—that is, about 138,000,000 of liquid superficies, and somewhat less than 60,000,000 of solid dry land. Of this land, the greater portion lies in the northern hemisphere, or north of the equator; while south of that line the ocean spreads for thousands of leagues, unbroken by a single islet. It will no doubt greatly alter this estimate should the indications of land within the antarctic circle hereafter prove to be portions of one great polar continent. The following is given as an approximation to the amount of land (in square

miles) in the different latitudinal *zones* of the earth's surface:—

Northern Hemisphere.		*Southern Hemisphere.*	
Arctic Zone,	3,250,000	Antarctic Zone,	———
Temperate Zone,	28,530,000	Temperate Zone,	3,830,000
Torrid Zone,	11,620,000	Torrid Zone,	12,210,000
Total,	43,400,000	Total,	16,040,000

The relative configuration of land and sea, we have said, is so extremely irregular, that no conception can be formed of it unless from the study of a well-constructed map; but whatever the character of this configuration, it exercises a most important influence on the physical operations of the globe, by determining the direction of oceanic and tidal currents, and by modifying the direction and force of waves. Oceanic currents influence the temperature, and consequently the life of the ocean; they carry along with them every species of floating débris—and this they deposit wherever the configuration of the land presents an obstruction. Tides also exercise a powerful transporting influence; they rise to greater or less heights, according as they are obstructed by the outline of the land; and while they sweep headlands and promontories bare, they lay down sand and gravel in sheltered bays. Waves also wear away the land, according as the line of coast obstructs or favours the violence of their progress. Since, therefore, these oceanic agents are wearing away dry land in one quarter, and filling up shallow bays and creeks in another; since rains and rivers are wearing down inland regions, and carrying the material to the sea; and since, moreover, earthquakes and volcanoes are here submerging land, and there elevating the bottom of the ocean—the relative distribution of land and water must be continually fluctuating. However imperceptible this shifting may be—little affected as the existing continents may have been within the historic period, or even within the era of man—still the change goes forward; and we are no more entitled to regard the present distribution as a thing fixed and enduring, than an inhabitant of the old red sandstone era—had any such existed—would have been to declare the then arrangement of land and sea as a thing immutable.

CONTINENTS AND ISLANDS.

The quarters or continents—though, strictly speaking, there are only the two great continents already mentioned—into which it is usual to divide the dry land, are *Europe*, *Asia*, and *Africa*, in the Eastern Hemisphere; North and South *America* in the Western; and *Oceania*—including Australia, Malaysia, and Polynesia—situated partly in both hemispheres. By referring to the map, it will be perceived that there are traces of land still unexplored both in the arctic and antarctic regions; but whether these may be islands or masses worthy to be ranked as new continents, we have yet few means of conjecture. At present, the comparative areas (in square miles) of the established quarters—including their respective islands—are calculated as follows:—

Old World, or Eastern Continent,		31,220,000
Europe,	3,724,000	
Asia,	16,152,000	
Africa,	11,354,000	
New World, or Western Continent,		15,000,000
North America,	8,200,000	
South America,	6,800,000	
Maritime World, or Oceania,		4,632,000

The superficies of this vast expanse presents an amazing diversity of character: some portions being little elevated above the sea-level, others rising into mountains of more than five miles in height; some tracts swampy, others arid; certain regions tame and flat, others diversified by the wildest irregularities; districts teeming, under tropical influences, with life and growth, others buried in the perpetual solitude of ice and snow. This diversity of character forms the especial object of our arrangement and description.

Although the above division into 'quarters' be convenient, and even justifiable enough, yet so much do these sections run into each other, so largely do portions of one or more of them lie within the same parallels, and so frequently are their other conditions akin, that it is not very easy to draw a series of broad and well-marked physical and vital distinctions between them. And yet there is something peculiar in the external conditions of Africa—for example, something in its climate and superficies, its river-systems, its Fauna and Flora—that serves to distinguish it as a whole from any of the other continents. The same may be said of South America, of North America, and of Oceania; and in a less degree of Asia and Europe, which are separated by no great natural boundary. Retaining, therefore, these generally acknowledged divisions, let us glance at their respective positions and superficial characteristics as influencing the vitality of our planet.

Europe—lying almost wholly within the northern temperate zone, diversified by a happy blending of mountain and plain, marked by no geographical feature on a scale so large as to give to its surface the character of monotony, and surrounded and intersected by seas which greatly influence its climate—affords, in proportion to its area, a habitat to a more varied and highly developed existence than any other quarter. Widely connected, however, with Asia on the east, those parts of the two continents that lie within the same parallels present considerable similarity, at the same time that every facility to the dispersion of species is afforded by a land communication. Asia, situated partly within the torrid, temperate, and frozen zones, and presenting an area almost five times that of Europe, exhibits every species of geographical diversity—vast mountain-chains and elevated table-lands, broad level steppes and sand deserts, luxuriant plains watered by the largest rivers, tracts doomed to everlasting snow or to scorching sterility, salubrious valleys of incessant verdure, and noisome jungles of the grossest growth. With such a variety of character, it is impossible to treat of it as a whole, and consequently geographers divide it into five well-marked regions—namely, *Central* Asia, consisting of a series of ascending plateaux, diversified by mountain-ridges of stupendous height, and intersected by narrow valleys; *Northern*, including the whole of the continent north of the Altaï Mountains—a flattish region traversed by large rivers, bleak and barren, suffering under an intense cold, thinly peopled, and almost physically incapable of improvement; *Eastern*—upon the whole a low-lying and somewhat arid region, though traversed by several of the largest rivers in the world, and occasionally diversified by spurs from the central table-heights; *Southern*, including the two peninsular projections of India within and without the Ganges—decidedly the finest region of the continent, diversified by minor hill-ranges and well-watered valleys, enjoying a high, though not an oppressive temperature, having only a rainy season for its winter, and, except during long drought, presenting in every district an unfailing verdure; and, lastly, *Western* Asia—from the Indus westward and north to the Caspian—which, with a few minor exceptions, may be said to consist of high sandy plains, studded with salt-lakes, very inadequately watered by rivers, and on the whole a hot and arid region. A continent marked by such a diversity of surface and climate, presents an appropriate field for the exhibition of almost every form of vitality known in the other continents; and thus has belief ever pointed to it as the cradle of organic existence. Africa, the next great division of the Old World, is almost entirely insular, the isthmus connecting it with Asia being only seventy-two miles across, of no great elevation above the sea-level, and even in part occupied by lakes and salt-marshes. Respecting the physical appearance and construction of Africa, our information is extremely limited; all that is known with any degree of certainty being some patches along the sea-board, and a few tracks

or lines across the Sahara, or Great Desert of the north. Little known, however, as it is, its isolation, its intertropical position, and its general configuration, must stamp it with *vital* peculiarities; and yet its connection with Asia on the one hand, and its proximity to Europe on the other—the Straits of Gibraltar being only about eight miles in width—offer numerous facilities to the interchange of vegetable and animal species. Thus the southern and northern sea-board of the Mediterranean present many similar forms; the Flora and Fauna of Egypt and Nubia are identical in many instances with those of the adjoining tracts of Arabia; while the intertropical regions offer numerous genera allied to those of Burmah and Hindostan.

Turning now to the New World, we find also the two Americas so slenderly attached by the narrow rocky Isthmus of Panama, which at one part is little more than eighteen miles across, that they may safely be regarded as separate and distinct continents. This separation is rendered still more decided by the irregular character of the isthmus and the adjoining high table-land of Mexico, which form an almost impassable barrier to the migration either of animal or of vegetable races. South America lies chiefly within the tropics, a third part or less stretching southward into the temperate zone; its superficies is broadly marked by mountain and plain, exhibiting along the entire western coast a flat arid region, from 50 to 100 miles in breadth; then rising boldly up into the Andes, which stretch along its whole length, and present a rugged irregular region of variable breadth; and ultimately falling away to the north and east in the *llanos* of the Orinoco, the *plains* of the Amazon, and the *pampas* of La Plata. Nor are its physical features more broadly marked than the plants and animals by which it is peopled, these exhibiting typical peculiarities only next in degree above those of the somewhat anomalous continent of Australia. The problem of the north-west passage being now solved, Greenland and a number of islands lying west of it might be conveniently erected into a new geographical division. Following, however, the usual course of including these regions, the area of the known continent of North America may be stated at 8,200,000 square miles—the great mass of which lies within the northern temperate zone. The general physical characteristics of the continent are remarkable for the magnitude of the scale upon which they are presented—the plains, lakes, and rivers being superior to those of all other countries. Though lying chiefly within the temperate zone, its southern and northern regions are respectively placed under tropical and arctic influences; and thus it presents in some measure the threefold variety of Fauna and Flora which characterises the greater continent of Asia. This greater diversity of climate renders it less peculiar in its living forms than the sister continent, at the same time that its proximity to Asia—being separated by Behring's Strait, which is only thirty-six miles broad—renders the immigration of Old-World species by no means improbable.

The *insular portions* of the globe are not less worthy of notice than the continents themselves, though these in reality are but islands of greater extent, washed on all sides by the ocean. Meaning, however, by the term *island* those smaller masses of land lying in the midst of seas and lakes, we find them sometimes solitary, oftener collected into groups or *archipelagoes:* in some cases they are little more than low sand-banks, ledges of rocks, or coral reefs; and in others—rising to a considerable elevation above the surface of the water, and spreading to a considerable extent—they present in miniature all the features of the continents to which they belong. They are often the summits of submarine mountain-chains, and, as such, are intimately connected with each other and with the neighbouring mainland. Many of them are evidently the production of volcanic forces—the dawn of new continents emerging from the waters, as others are the gradually submerging relics of former terrestrial regions. The most important island-groups are the British, Japan, Philippine, and East Indian in the eastern hemisphere; and the West Indian and Polynesian in the western. The largest individual islands (regarding Australia as a continent) are—Borneo, with an area of about 260,000 square miles; Madagascar, 234,000; New Guinea, whose outline is yet imperfectly known; Sumatra, 128,000; Niphon, 109,000; Great Britain, 83,828; Nova Zembla, 25,000; Newfoundland, 57,000; Cuba, 43,400; and Iceland, 30,000 square miles.

Islands, we have said, are either connected with existing continents, are portions of former continents now submerged, or are new and independent elevations. Thus, if an island is of the same geological formation with the adjoining mainland, we must regard it either as a portion separated by depression, or as a belated portion only rising into dry land. In either case, we are bound to consider it in all its relations—vital as well as physical—as belonging to the adjacent continent. Again, islands of totally different formation from that of the nearest continent may in most cases be regarded either as relics of former lands, or as new lands rising into day; and we are not to be startled at the fact of their exhibiting—like Australia—races of plants and animals altogether peculiar. Lastly, with respect to far distant and solitary islets, whether of volcanic origin or not, we must view them as indices of operations past or future, and as proofs of the fact that the sea-bottom presents the same irregularities as the surface of the land—these islets towering above the general configuration like the lofty peaks of existing mountain-ranges.

Such is a brief glance at the partition of the dry land (so far as it is known) into continents and islands—a partition which exercises an all-important influence over organic existence, and which, after all, is dependent on very minute geological operations. A general elevation of the solid crust in the eastern hemisphere, for example, would connect Britain with the continent of Europe, the Lofoden Islands with the Scandinavian peninsula, enlarge the connection between Asia and Africa, elevate the Sunderbunds of the Ganges into a vast plain, the Laccadive and Maldive reefs into extensive islands, and the bed of the Yellow Sea into an alluvial plain. A depression to the same amount, on the other hand, would sever Scandinavia from Europe, lay the Netherlands and part of Central Europe under water, sever Africa from Asia, convert a large portion of Arabia, Egypt, and Northern Africa into an extension of the Mediterranean; in fact, totally overturn the existing relationship of the dry land in the Old World. Similar phenomena would be presented under similar circumstances in the New World; and more strikingly still in connection with the island-groups of the Pacific. Equally important results depend upon the relative positions of the continents and islands. Had South America, unaltered in a single square yard, lain parallel with, instead of crossing, the equator, or had Africa been intersected by seas, as Europe is, it requires no stretch of imagination to conceive the radical difference which their Flora and Fauna would have presented. Whether the present arrangement of continent and island is that which admits of the greatest amount and variety of vital development, is what we have not yet sufficient data to determine; but this we know, that the existing irregularity and varied subjection to arctic, temperate, and tropical influences, are much more favourable to these results than any single influence, however gigantic its operation. Nay, more, as regards man, and the highest aim of creation—the civilisation of man—the present arrangement is of the first importance. The theatre of his operations all arctic, and he would never have risen above the condition of the Laplander or Esquimaux; all antarctic, and behold his condition in that of the miserable Fuegian; all tropical, and see him in a state of languid, enervated, semi-civilisation;

while balanced as conditions are, see his progress mainly in one broad zone, where Chinese, Indian, Persian, Chaldean, Syrian, Egyptian, Greek, Roman, Frank, and Anglo-Saxon have successively or simultaneously figured in the march of improvement.

MOUNTAINS AND TABLE-LANDS.

As elevation above the waters of the ocean is the origin of the dry land, so its most prominent features are those peculiar upheavals known by the name of *hills* and *mountains*. They are the framework, so to speak, upon which the solid crust is built and compacted; they are the immediate results of the elevating forces mentioned under GEOLOGY; and according to their character, so is that of the regions to which they belong, generally speaking, determined. They subserve numerous and important purposes in nature. Rising into regions of perpetual ice, they serve, in hot climates, to temper the air with the breezes generated around their heights; they are the reservoirs of rivers, supplying the shrinking streams, in the dry seasons of the lower countries, with copious torrents from their melting snows; they are in most instances the storehouses of the richest minerals; they increase and diversify the surface of the earth; and, by presenting impassable barriers between opposite regions, they give variety and richness to animal and vegetable life: we say impassable barriers, for the broadest seas are not half so effective in obstructing the dispersion of vegetable and animal life as lofty snow-clad mountains. Seas have their tides and currents, and drifting winds and waves—even the polar seas have their firm ice-fields and drifting ice-floes, on which plants and animals may be borne; but the snow-clad summit is enduringly inapproachable by everything that partakes of vitality.

Isolated mountains of great height are of rare occurrence, and when they do appear, are usually active or recent volcanoes. Hills and mountains, whether rising to the height of 1000 or 20,000 feet, generally appear in chains or ranges, consisting either of one central chain, with branches running off at right angles, or of several chains or ridges running parallel to each other; and in both cases often accompanied by subordinate chains of minor elevation. Several chains constitute what is called a *group;* and several groups, a *system*. Geology views these systems as so many axes of elevation, necessary to the rise of certain formations from the bottom of the ocean; ascertains the direction and centre of the elevating force; explains the phenomenon of 'crag and tail;' speculates on the cause of the steep side being generally turned towards the older formations, while the gradual slope looks towards the newer; and further determines the respective eras when they rose into existence, by examining the nature of the stratified deposits broken through and carried up with the elevatory masses. Thus the Grampians, flanked and crested by no secondary rocks, long preceded the Pyrenees; the Pyrenees the Alps, which displaced the youngest secondary strata; and the Alps, again, had risen into form while the site of Etna was a shallow sea of tertiary deposit. The relative ages of mountain-chains appertain more especially to the province of the geologist; but with their epochs is connected their physiognomy or contour, a subject eminently interesting to the geographer. So persistent is the contour of mountains, whether associated with the primitive, secondary, or more recent formations, that the practised eye of the geologist can generally determine at a glance the era of their upheaval. The bold, but bald and massive heights of a granitic mountain differ widely in aspect from the abrupt and splintery crags and pinnacles of a primitive; while the rounded, undulating, and terraced outline of the secondary trap-hills distinguishes them at once from the conical crateriform heights of the tertiary era. Nor is it in appearance alone that these distinctions are interesting; the cold barren subsoil of a granitic district, altogether independent of elevation, differs as widely in its vegetable exhibitions from those of a fertile and congenial trap, as a cultured garden does from a moorland wild.

Respecting the classification of mountains, various plans have been adopted by continental writers; but most of them are objectionable, as involving geological theories: we shall adhere to that simpler arrangement which takes into account merely their geographical position and connection. Those of Europe have been classified into a number of systems, some of which are continental, others insular. Laying aside minutiæ, the following seem to be distinct and natural:—1. The *Hesperian*, embracing the mountain-ridges of the Spanish peninsula—all of which maintain a wonderful parallelism in position, as well as unity of character, and whose extreme culminating-point is Maladetta, in the Pyrenees, 11,424 feet. 2. The *Gallo-Francian* system, including all the hilly eminences in France which lie to the north of the Garonne, west of the Rhône, and south of the Rhine. None of these are of great age, or of great elevation, the highest being a peak of the Plomb de Cantal, in Auvergne, 6113 feet. 3. The *Alpine* system, embracing all those ridges and branches which radiate from the great Alpine range of Switzerland, such as the Maritime, Cottian, Pennine, Rhetian, Noric, and other Alps; the Apennines in Italy, and the Balkan or Hæmus group in Turkey. This is the great mountain development of Europe, under which, as one system, geographers used to comprehend the whole of the southern groups and chains: the highest or culminating-point is Mont Blanc, in Switzerland, 15,732 feet. 4. The *Hercynio-Carpathian* system, including all the mountains and eminences comprehended between the Rhine, Dnieper, and Danube, the plains of Northern Germany and Western Poland. The highest point in this system is Lomnitz, in the Central Carpathians, 8540 feet. 5. The *Scandinavian*, a system of the highest antiquity, embracing the well-defined chains of Norway, Sweden, and Lapland, the extreme height of which does not much exceed 8000 feet. 6. The *Ural* system or chain, which forms the boundary-line between Europe and Asia, and rises in its highest part to between 5000 and 6000 feet. Lastly, the *Britannic* system, consisting of a number of detached chains, as the Grampians, Cheviots, and Welsh mountains, the highest point of which is Ben Nevis, in Inverness-shire, 4406 feet. All of these systems, as axes of elevation, have long ago become fixed and permanent; none of them has for the last two thousand years shewn symptoms of volcanic activity: Hecla, Vesuvius, and Etna, the only active volcanoes in Europe, seem to point to future upheavals.

The mountains of Asia may be all traced from that vast central plateau already adverted to, which forms, as it were, the nucleus of the continent. Omitting ranges of minor altitude, we may enumerate—the *Altai*, forming the boundary between the Chinese Empire and Siberia, one of the bleakest ranges in the world, stretching unbroken for 500 miles in length, and reaching an extreme altitude of 11,500 feet; the *Yablonoi* and *Stanovoi*, which may be regarded as prolongations of the Altaï, stretching onwards to Behring's Strait, and attaining a height probably not exceeding 6600 feet; the *Khing-khan* range, bounding the Desert of Kobi, extending about 800 miles in length, but of unknown altitude; the *Chang-pe-shan*, skirting the east coast of Manchooria, and rising abruptly from the sea to a height of 5000 feet; the *Pe-ling* and *Yun-ling* ranges, on the west of China Proper, ramifying variously, probably attaining a culminating height of 11,000 or 11,500 feet, and branching southward through Burmah and Anam in several parallel ridges which fall to 4000 and 3000 feet; the great *Himalaya* mass, extending about 1500 miles in length, and from 200 to 250 across, rising from the Indian side by stages of 4000, 8000, and 11,000 feet, to a mean elevation of 18,000 or 20,000 feet, attains in several peaks the height of about 25,000,

in Dhwalagiri 28,000, and in Kinchinjunga 28,176—probably the greatest elevation on the globe; the *Hindoo Coosh*, with their southern ramifications, which may be regarded as prolongations of the Himalaya; the *Thian-chan*, in Central Tatary, rising to an absolute height of 11,000 or 12,000 feet, but only from 3000 to 4000 above the surrounding table-land; and, lastly, the *Tauro-Caucasian* system, diversifying the west of Asia with numerous ridges and peaks, the highest of which is Elburz, 17,796 feet. In connection with these systems and ridges are active volcanoes, as in Kamtchatka, Japan, the Thian-chan ranges, the plateau of Mongolia, &c.; and we are therefore not entitled to regard those so connected as having yet attained their ultimate stage of elevation.

The mountain-systems of Africa are as yet only partially known. The hills of Cape Colony rise from Table Mount, 3582 feet, to the summits of the Nieuveldt and Snieuveldt mountains, in the north of the colony, which are estimated at 7000–10,000 feet; the spaces between the ranges being shrubby *kloofs* or valleys, and broad elevated terraces or *karoos*. Beginning with Cape Colony, one vast table-land, the greatest on the globe, occupies the south of the African continent, stretching on the east as far north as Nubia. The mountain-ranges seen running parallel with the east coast, form the border of this table-land; the highest of them yet seen is Kilimandjaro, between 3° and 4° south latitude, estimated at 20,000 feet. The Abyssinian mountains form a terminating cluster to the range, reaching in the Abba Yared, at the extremity of the table-land, the height of 15,000 feet. The Cameroons, on the west, are above 13,000 feet. On the north, between the Sahara and the Mediterranean, the *Atlas* system is well defined, and here an elevation of 11,400 feet has been ascertained; but some peaks in the chain rise much higher, and are permanently covered with snow—a fact which would seem to indicate an altitude of more than 15,000 feet.

The mountains which traverse South America may be ranked under two systems—the *Cordilleras* or *Andes* proper, and the *Brazilian Andes*. The former, in several parallel chains, extend from the Straits of Magellan to the Caribbean Sea, in many places spreading out over a breadth of several hundred miles, embracing lofty table-lands, containing mountain lakes, and everywhere intersected by steep narrow ravines, passes, and lofty water-falls. At Popayan, the main chain divides into three ridges, one of which, shooting off to the north-west, passes into the Isthmus of Panama; a second separates the valleys of the Cauca and Magdalena; and a third, passing off to the north-east, separates the valley of the Magdalena from the plains of the Meta. The highest summits of the system are in the Chilian Andes, between 37° and 31°, where Aconcagua, the highest volcano in the world, and now believed to be the highest summit of the chain, reaches the elevation of 23,200 feet. Chimborazo and Sorata, in the equatorial and Peruvian Andes, are respectively 21,424 and 21,286. Altogether, the Andes present a most magnificent spectacle to the voyager on the Pacific; the snow, which permanently covers their lofty summits, even under the burning sun of the equator, contrasting beautifully with the deep blue of the sky beyond; while occasionally another contrast is exhibited in vast volumes of smoke and fire, emitted from some of the numerous volcanoes which stud the entire range. The Brazilian mountains occupy a great breadth of country, but seldom exceed an elevation of 6000 feet.

The mountains of North America are scarcely in proportion to the other physical features of that continent, either in point of continuity or of altitude. Regarding the Cordilleras of Panama and Mexico, the Californian or Maritime range, and the Rocky Mountains, as portions of the great system of the *Andes* proper, we have in Guatemala a culminating-point of above 13,000 feet; in the Mexican volcano of Popocatepetl, of 17,735; in the table-land of Mexico, a general height from 4000 to 8000 feet; and in the Californian range, an average altitude of 8000 or 10,000 feet. The *Rocky Mountains*—the greatest and most continuous of the North American chains—rise from 8000 to 10,000, occasionally to 12,000, and only between 52° and 53° north, to 16,000 feet; while the *Alleghanies* reach their extreme height at 6476 feet, and sink down in their branches to 3000 and 2000 feet.

In Oceania we have several minor groups and ranges; but the principal elevations are in detached volcanic heights, the index-fingers, as it were, to future mountain-systems. In Malaysia, the highest known point is Mount Ophir, in Sumatra, 13,850 feet; Australia has no eminences of importance; but Polynesia has the verdant and wooded heights of Tahiti, rising to 8000 feet; and the active craters of Owyhee, above 13,000.

Such are the more prominent mountain-systems as known to geography. Those who regard them as mere ridges, rising on one side, and descending as abruptly on the other, and at most intersected by a few narrow passes, gorges, and ravines, form a very erroneous conception of the physical contour of the globe; for, so far from this being the case, most of these systems are but the escarpments or ramparts of elevated expanses known as *plateaux* or *table-lands*, which form in some instances the nucleus of continents, and the source from which the rivers of such continents flow. Thus, on examining the map of Asia, it will be seen that all the rivers flow—north, east, south, and west—from the central region, which in reality forms a succession of remarkable plateaux. These plateaux may be termed the Persian, which ranges from 3000 to 6000 feet above the sea; the Mongolian, at an elevation of from 8000 to 12,000 feet; and that of Tibet, which reaches 17,000. There are some masses of this kind in Europe, but of comparatively small extent—as the central part of Spain, which is about 2200 feet in height; and the Swiss table-land, between 3000 and 4000 feet. Of the elevation of the great South-African plateau, we cannot speak precisely, but it seems to be highest towards the borders. In South America, the city of Potosi, in Bolivia, is situated in the elevated valley of Desaguadero, at 13,600 feet above the sea-level; and the plateau on which Quito stands has an elevation of 9000 feet. One of the most noted table-lands is that of Mexico, not less remarkable for its elevation than for its extent. 'On the eastern and western coasts are low countries, from which, on journeying into the interior, you immediately begin to ascend, climbing, to all appearance, a succession of lofty mountains. But the whole interior is, in fact, thus raised into the air from 4000 to 8000 feet. The conformation of the country has most important moral and physical results; for while it gives to the table-land, on which the population is chiefly concentrated, a mild, temperate, and healthy climate, unknown in the burning and deadly tracts of low country into which a day's journey may carry the traveller, it also shuts out the former from an easy communication with the sea, and thus deprives it of a ready access to a market for its agricultural productions.' As with the Mexican, so with all other table-lands, according to their latitude and elevation: under the tropics they become theatres for the exhibition of temperate or even of arctic species; while under a temperate zone they are inhabited solely by boreal forms.

EARTHQUAKES AND VOLCANOES.

These are rather agents than effects—rather the cause of geographical diversity than geographical features themselves; and in this respect belong more properly to the province of geology: still, as by far the greater portion of superficial irregularity is the direct result of their operations, and as it is often impossible to separate cause from effect, it will be necessary here to give them some further consideration. An earthquake may produce a momentary undulation of the ground, followed by no perceptible result; it may simply elevate one region or depress another; it may be attended by a vast destruction of animal life, and the submergence of forests; it

may alter the course of rivers, and produce new shores and beaches; it may create vast tidal waves, which give rise to accumulations of débris; open new springs and fissures, from which issue various products differing from those hitherto known in the district. Innumerable instances of such changes could be cited; a few, however, will suffice to convince the reader of the importance of this class of physical agencies:—By the great Chile earthquake of 1822, an immense tract of ground—not less than 100,000 square miles—was permanently elevated from two to six feet above its former level; and part of the bottom of the sea remained bare and dry at high-water, with beds of oysters, muscles, and other shells adhering to the rocks on which they grew, the fish being all dead, and exhaling most offensive effluvia. By an earthquake in 1819, a tract—the Ullah-bund—in the delta of the Indus, extending nearly fifty miles in length and sixteen in breadth, was upheaved ten feet; while adjoining districts were depressed, and the features of the delta completely altered. The earthquakes of Calabria, which lasted for nearly four years—from 1783 to the end of 1786—produced numerous fissures, landslips, new lakes, ravines, currents of mud, falls of the sea-cliffs, and other changes, which, taken in conjunction, afford one of the finest examples of the complicated alterations which may result from a single series of subterranean movements, even though of no great violence. In 1743, the town of Guatemala, in Mexico, with all its riches, and 8000 families, was swallowed up, and every vestige of its former existence obliterated—the spot being now indicated by a frightful desert, four leagues distant from the present town. In 1692, a similar calamity overtook the town of Port Royal, in Jamaica, when the whole island was frightfully convulsed, and about 1000 acres in the vicinity of the town submerged to the depth of fifty feet.

Volcanic forces act in a similar manner, in as far as they elevate, depress, and break asunder portions of the earth's crust; indeed, earthquakes and volcanic throes, considered as subterranean movements merely, produce precisely the same results. But volcanoes, properly so called, act in another and equally important manner in producing geographical changes. They elevate the crust into long continuous ridges or mountain-chains, form isolated cones, and discharge accumulations of lava, scoriæ, ashes, loose stones, and other igneous débris. Geologists and geographers often amuse themselves by enumerating volcanic vents to the amount of 300 or thereby; but this is of little moment compared with the determination of the centres of elevation to which they belong. In Europe, there appear to be three centres of volcanic action—namely, that of the Levant, to which Etna and Vesuvius belong; that of Iceland, represented by Hecla and the craters of Jan Meyen; and that of the Azores, in the Atlantic. In Asia, there is abundant evidence of volcanic action on the borders of the Mediterranean, the Black Sea, the Caspian, and the Persian Gulf; while along the eastern borders of that continent there is a range not less than 5000 miles in length, and 250 in breadth, including Sumatra, Java, the Eastern Moluccas, and the Philippine Islands; the same range bearing further northward, though less distinctly, for several thousand miles, and terminating in the volcanic cones of the Aleutian Isles. The whole extent of the two Americas is also traversed by a volcanic range, manifesting itself by eruptions along the whole line, from the Rocky Mountains, through Mexico and the Andes, onward to Patagonia and Tierra del Fuego. The islands of the Pacific further attest the presence of similar forces, as in the New Zealand, Sandwich, and other groups; as do those—namely, the Canaries, Cape de Verd, Ascension, St Helena, Madagascar, Bourbon, &c.—which surround the continent of Africa. In these centres of igneous action, many of the volcanoes are *extinct*, others are merely *dormant*, while many are incessantly *active*.

The cause of volcanoes, earthquakes, and other subterranean movements, has been the subject of several theories, but is yet by no means very satisfactorily determined. The most prevalent opinion is that which connects them with one great source of central heat—the residue of that incandescent state in which our globe originally appeared. By this hypothesis it is assumed that the crust of the earth is of various thickness, that it contains vast caverns, and is extensively fissured—primarily by unequal contraction from cooling, and subsequently by subterranean agitations. Through these fissures, water finds its way to the heated mass within; this generates steam and other gases, and these exploding, and struggling to expand, produce earthquakes and agitations, which are rendered more alarming by the cavernous and broken structure of the crust, and the yielding material upon which it rests. Occasionally these vapours make their way through fissures and other apertures as gaseous exhalations, or as hot springs and jets of steam and water, like the geysers of Iceland. On the other hand, when the expansive forces within become so powerful as to break through the earth's crust, discharges of lava, red-hot stones, ashes, dust, steam, and other vapours follow; and repeated discharges of solid material gradually form volcanic cones and mountain-ranges. It does not follow, however, that volcanic discharges must always take place at the point where the greatest internal pressure is exerted, for volumes of expansive vapour press equally upon the crust and upon the fluid mass within, so that the latter will be propelled towards whatever craters or fissures do already exist. This theory of central heat is further supported by the occurrence of igneous phenomena in all regions of the globe, and by the fact that most volcanic centres are in intimate connection with each other—a commotion in one district being usually accompanied by similar disturbances in another. The only other hypothesis which has met with countenance from geologists is that which supposes the internal heat to be the result of chemical action among the materials composing the earth's crust. Some of the metallic bases of the alkalies and earths, as potassium, the moment they touch water, explode, burn, melt, and become converted into red-hot matter, not unlike certain lavas. This fact has given rise to the supposition that such bases may exist within the globe, where, water finding its way to them, they explode and burn, fusing the rocks among which they occur, creating various gases, and producing caverns, fissures, eruptions, and other phenomena attendant upon earthquakes and volcanoes. As yet, our knowledge of the earth's crust at great depths is excessively limited; we know little of the chemical and magnetic operations which may be going forward among its strata; and we are equally ignorant of the transpositions which may take place among its metallic and earthy materials; but, judging from what we do know, this theory, however ingenious, seems by no means adequate to the results produced. It is true that there occurs nothing among the products of volcanoes at variance with its assumptions; but the magnitude, the universality, and the perpetuity of volcanic action, point to a more stable and uniform source—that source being the internal heat or residue of that igneous condition in which our planets originally appeared.

PLAINS—VALLEYS—AND OTHER DEPRESSIONS.

The plains, or level portions of the earth's surface, form a feature in its physical aspect equally important with that presented by its mountain-systems. The name is given to extensive tracts whose surface in the main is level, or but slightly broken by elevations and depressions. They are found at all elevations above the sea, and of every degree of fertility; from the exuberant tropical delta just emerging from the water, to the irreclaimable sterility of the desert of ever-shifting sand. In the economy of nature, they constitute the chief theatres of vitality: there, plants, from the lowliest herbage to the most gigantic timber-trees, flourish in greatest perfection and abundance; there, animals,

governed by food-instincts, congregate most densely; and there, man, led by similar instincts, and by the higher purposes of social life, has chiefly planted his habitation.

The noblest of these expanses are the river-plains of the New World, drained by such waters as the Mississippi, the Amazon, and La Plata. In North America, the basin or drainage of the Mississippi is estimated at 1,300,000 square miles, and that of the St Lawrence at 600,000; while northward of the fiftieth parallel extends an inhospitable flat of perhaps still greater dimensions. Much of the former expanse is rolling or undulating in its surface, well watered by minor rivers, exhibiting broad grassy *prairies* and extensive pine-forests; the second is more irregular in surface, largely occupied by lakes, and cumbered with forest-growth; while the last is a bleak and desolate waste, overspread with innumerable lakes, and resembling Siberia in the physical character of its surface and the rigour of its climate. In South America we have first the low belt of country skirting the shores of the Pacific, from 50 to 100 miles in width, and about 4000 in length, fertile at its extremities, but in the middle sandy and arid; next, the basin of the Orinoco, consisting of extensive plains called *llanos*, either destitute of wood, or merely dotted with trees, but covered during part of the year with tall herbage; then the basin of the Amazon, a vast plain, embracing a surface of nearly 2,000,000 square miles, possessing a rich soil and humid climate, and almost entirely covered with dense forests and impenetrable jungle-marshes by the river-sides; and, lastly, the great Valley of the Plata, occupied chiefly by open plains called *pampas*, in some parts saline and barren, but in general clothed with weeds, thistles, and tall grasses. Next, in order of importance, is that section of Europe extending from the German Sea, through Prussia, Poland, and Russia, towards the Ural Mountains, presenting indifferently tracts of heath, sand, and open pasture, and regarded by geographers as one vast plain. So flat is the general profile of this region, that it has been remarked, 'it is possible to draw a line from London to Moscow, which would not perceptibly vary from a dead level!' Passing the Ural ridge, a plain of still greater dimensions stretches onward through Siberia, towards the shores of the Pacific. This region is of no great elevation, and, though diversified by occasional heights, consists chiefly of gravelly steppes, covered with coarse herbage, lakes, and morasses. In Africa, the northern and central portion, so far as explored, appears to be a vast expanse of Sahara, or sandy desert, broken at scanty intervals by oases of life and verdure.

Besides these wide expanses, which may be said to counterbalance the mountain-systems, there are plains of minor extent, which often stamp the countries to which they belong with a peculiar character. These are the verdant *prairies* of North America, already noticed, the *pampas* and *llanos* of South America, the *steppes* of Asia and Northern Europe, the *tundras* or bog-marshes of Siberia, the grassy *karoos* of Southern Africa, the tangled *jungles* of India, the alluvial *straths* or *dales* of our island, and the low muddy, but gradually increasing *deltas* of such rivers as the Ganges, Nile, Niger, and Mississippi. To lesser flats and depressions—as valleys, glens, ravines, &c.—which give character to the landscape of minor districts, our space will not permit us to refer. Physically, they produce results akin to those of larger depressions; and whether they be the subsidences occasioned by earthquakes, the sites of silted-up lakes, valleys of erosion, or ravines of volcanic rupture, it is the province of geology, not of geography, to determine.

Under this head it is usual to describe *fissures*, *caverns*, and other *subterranean* openings; but as these are interesting more on account of their curious structures, than from any effect they produce on the aspect or conditions of the globe, we shall leave them to be noticed, as occasion may offer, under the respective countries in which they occur. This only we may observe, that they owe their formation either to earthquakes and volcanic convulsions, to the erosion of subterranean springs and streams, or to the action of waves and tides, when the cliffs in which they are situated formed the shores of the ocean. They become indices, in this way, to bygone operations; and are not unfrequently the catacombs, as it were, of animals long ago extinct, whose remains had either been drifted thither, or who, while alive, had fled there for a last shelter during some of nature's extraordinary convulsions.

THE OCEAN.

The ocean, though in fact a single mass of fluid resting in the hollows of the solid crust, surrounding the dry land on all sides, and indenting it with numerous bays and gulfs, is generally divided by geographers into the following great basins:—The *Pacific* Ocean, 11,000 miles in length from east to west, and 8000 in breadth, covering an area of 50,000,000 square miles; the *Atlantic*, 8600 miles in length from north to south, and from 1800 to 5400 in breadth, covering about 25,000,000 square miles; the *Indian* Ocean, lying between 40° south, and 25° north latitude, is about 4500 miles in length, and as many in breadth, covering a surface of 17,000,000 square miles; the *Antarctic* Ocean, lying round the south pole, and joining the Indian Ocean in the latitude of 40° south, and the Pacific in 50°, embraces an area—inclusive of whatever land it may contain—of 30,000,000 square miles; and the *Arctic* Ocean, which surrounds the north pole, and lies to the north of Asia and America, having a circuit of about 8400 miles. Besides these great basins, there are other *seas* of considerable extent, as the Mediterranean, covering an area of 1,000,000 square miles; the German Ocean, 153,700; the Baltic, 134,900; the Black Sea, with its subordinate gulfs and branches, 181,000; but these, and other minor sections, will be more appropriately described when we come to treat of the respective countries (Volume II.) with which they are politically as well as physically associated.

Respecting the *depth* of the ocean, we have no very definite knowledge; but this we may assume, *a priori*, that it possesses great irregularity of depth and shallowness, just as the terrestrial surface presents diversity of hill and plain. It is also thought probable, considering the greater extent of the ocean than of the land, that the greatest depths of the former may considerably exceed the greatest elevations of the latter; and this would seem to be borne out by recent deep-sea soundings, if their accuracy could be depended upon. In the North Atlantic, 31° 59′ north latitude, 58° 43′ west longitude, no bottom was found with a line of 34,200 feet, or 5·6 geographical miles; but in 36° 49′ south latitude, 37° 6′ west longitude, bottom was found at the depth of 46,236 feet, or 7·6 geographical miles. Lieutenant Maury believes the greatest depth yet surely ascertained, to be not more than 25,000 feet. The deepest place in the North Atlantic is immediately to the south of the Grand Banks of Newfoundland. Having nearly ascertained its superficies, and assuming average depths, many have amused themselves with calculating the probable quantity of water in the ocean; but all such calculations, in the absence of anything like data, are worse than worthless. This only we know, that the quantity, whatever it may be, remains, by the unalterable laws of evaporation and condensation, always at a fixed point, there being neither increase nor decrease. It has been remarked by La Place, a French astronomer, that if the existing waters of the ocean were increased only one-fourth, the earth would be drowned, with the exception of some of the highest mountains; and that if, on the other hand, the waters were diminished in the same proportion, the largest rivers would dwindle to the capacity of brooks, and some of the principal arms of the sea would entirely disappear, while at the same time the earth would be deprived of its due proportion

of humidity, and the face of nature be dried up and rendered desolate. The *pressure* of the ocean—which depends on its depth—exerts an important influence, inasmuch as it renders it impossible for plants or animals to exist beyond a comparatively limited distance from the shore or depth from the surface. Teeming as the ocean is with life, its greater depths seem to be as void and desolate as the peaks of the snow-clad mountains.

Water being a slow conductor of heat, the *temperature* of the ocean is less affected by seasonal influences, and much more uniform, than that of the atmosphere; while the action of currents and counter-currents tends to equalise its heat in all latitudes. Within the tropics, the surface-temperature ranges between 77° and 84° Fahrenheit; but at the depth of 300 feet or thereby, the solar influence is unfelt. In the torrid zone, the temperature diminishes with the depth; in the polar seas, it increases with the depth; and about the latitude of 70°, it is nearly constant at all depths. Taking the month of March as one of those during which the heat of the sun must be equally determined in both directions by latitude, we find that in that month the sea has been found, at 11° 32′ south, of 80·6 Fahrenheit; at 31° 34′ south, of 75·7; at 40° 36′ south, of 59·9; though in some instances it has been found several degrees more or less at the same season, and under nearly the same latitude. A small difference is discovered between the observations on temperature in the two hemispheres. For the first twenty-five degrees towards the south, the decrease of heat is slower, and after that more rapid, than towards the north. It must be evident to every one who considers the great mass of waters composing the ocean, and the interchange of position which must always be taking place, to a greater or less extent, between the warmer and colder portions, that this comparative equability of temperature is unavoidable, even if there were no other causes to account for it. The uses of that equability are still more obvious: by it the natural result of high latitude is more or less corrected. A milder air breathing from the sea softens the climate all over the adjacent land, and produces a congeniality which is of the greatest service. On the other hand, in those torrid regions where both animated and vegetable nature is apt to sink beneath the vertical rays of the sun, the cooling breath of the ocean comes, generally at regular intervals, communicating freshness and vigour to all around.

The *saline property* of the ocean, to which we have already adverted in general terms (p. 51), has never been scientifically accounted for; it baffles all human investigation. Some have alleged that it is caused by fossil or rock salt at the bottom; others, that the saline constituents are carried down by springs and rivers from the land; but neither hypothesis will account for all the phenomena; while, if the latter were true, the ocean would be gradually becoming salter in consequence of incessant contributions. The most reasonable conclusion is, that the sea has been from the first a salt body; that its waters were created, and have continued, and ever will continue, in this saline condition, in the same manner that the atmosphere has been created and exists as a compound body. The inquiry, therefore, why the sea is salt, is just as needless as why the atmosphere is composed of two or three gases. The two questions are equally shrouded in mystery. All that we know for certain is, that the ocean is not of uniform saltness; that the Southern Ocean, for example, contains more than the Northern; that inland seas are sometimes more, sometimes less, saline than the open ocean; and that the surface-water is somewhat fresher than that obtained from considerable depths. The gravity conferred on the water of the ocean by its saline property is 1·027, reckoning distilled water at 60° Fahrenheit equal to 1; and to this density it owes its superior buoyant powers. Again, fresh water, under ordinary circumstances, freezes at 32° Fahrenheit, whereas the water of the ocean requires a degree of cold equal to 28°; and the ice then formed is irregular, porous, and charged with vesicles full of a dense briny liquid.

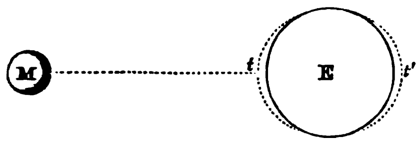
The *colour* and *phosphorescence* of the ocean are the next sensible properties requiring attention. When examined in small quantities, sea-water is colourless; but when viewed in the mass in the wide ocean, it appears to be of an azure or blue tint. The cause of this generally blue colour has not been as yet clearly explained; but it seems to be in some degree accounted for by reference to certain principles connected with the science of optics. Probably most are aware that light consists of the set of colours which we see so beautifully displayed in the rainbow. Now, it is a law of light, that when it enters any body, and is either reflected or transmitted to the eye, a certain portion of it, consisting of more or less of its colours, is lost in the body. The remainder, being reflected, strikes our vision, and whatever colour that may be, the object seems of that colour. Now, it chances that the portion of light most apt to be reflected from masses of transparent fluid is the blue; hence it is supposed to be that the air and sea both appear of this colour. While there can be no doubt that the ocean is generally of a blue colour, it is equally certain that there are many portions of sea in which a different hue appears. The causes of those exceptions from the rule seem to be of various kinds. Frequently the ordinary colour of the sea is affected by the admixture of foreign substances, these being sometimes of a living and organic nature, and sometimes not. The most simple example of the latter class of cases is the common flooding of any stream, when quantities of mud and earthy particles are introduced into the river, and emptied into the sea. What is thus strikingly seen on every coast, on a small scale, will readily be conceived to be of infinitely wider extent in the mighty rivers of the principal continents of the globe. Some seas are coloured *yellow* from a similar cause. Vegetable matter is known to have a colouring effect; but more usually the peculiar tint, whether red, green, &c., of the sea, results from the presence of infusorial animalcules. Another class of cases in which the ocean appears to be tinged with a peculiar colour, is referable to the reflection of rays of light from the bed or bottom; and hence, in shallow and clear seas, the colour of the ground is a main cause of any particular tint which the water may there assume.

The phosphorescence of the ocean, described in such glowing terms by almost every voyager in tropical seas, is now satisfactorily ascertained to arise sometimes from the presence of infusorial animalcules, and at others from the decomposition of vegetable and animal matter. Similar phenomena, arising from similar causes, exist on land—the glowworm, firefly, certain fungi, putrid fish, &c.—and their appearance in the one element need not excite greater surprise than their exhibition in the other.

TIDES—CURRENTS—WAVES.

The waters of the ocean are subject to various motions and fluctuations, such as tides, currents, whirlpools, waves. That regular ebb and flow known by the name of *tides*, and which confers on the ocean one of its most interesting features, is caused by the attraction of the sun and moon. By the universal law of gravitation, all masses of matter have a tendency to be attracted or drawn towards each other. The moon, therefore, as a mass of matter, in passing round the earth, has a tendency to draw the earth after it, or out of its natural relative position; and it really does so to a small extent. As it passes round, it draws up the waters in a protuberance, or, in common language, draws a huge wave after it. But it also draws the whole solid globe—though to a less extent than the water immediately under it—and so causes the opposite side of the globe to be drawn away from the ocean, leaving the waters

there to form a similar protuberance or high wave. In the one case, the water is drawn directly up or towards the moon (M); in the other, the water is in some shape



left behind by the land being pulled away from it. In both a similar effect is produced: two tides (*t*, *t'*) are caused at opposite extremities of the earth. Where the higher part of either of these great billows strikes our coasts, we have the phenomenon of high-water; and when the lower touches us, it is low-water. Each of the waves is brought over any given place in the circumference of the earth in twenty-four hours, so as to cause high-water twice a day. The sun exerts a far greater attractive influence on the earth than the moon does; but from the great distance of that luminary, the *difference* of that attractive force on different parts of the globe is much less, and therefore the effect is comparatively small. But when this minor influence of the sun coincides with that of the moon, or acts in the same line of attraction (M*t*), we perceive a marked increase in the tides; on such occasions we have what are called *spring* or *large* tides. When the solar and lunar attractions act in opposition, we have *neap* or *small* tides. The spring-tides happen twice a month, when the moon is at full and change; and the neap when the moon is in the middle of its orbit between those two points. A tide requires six hours to rise—which it does by small impulses or ripplings of the water on the shore—and six hours to ebb or fall; but every successive high-water is from twenty to twenty-seven minutes later than the preceding, or, on an average, about fifty minutes for two tides, in consequence of the earth requiring that time above the twenty-four hours to bring any given point again beneath the moon. The tides are thus retarded by the same reason that makes the moon rise fifty minutes later every day. It is evident that the tides will be greatest at that point of the earth's surface which is nearest to the moon, or where the latter is vertical. She is so between the tropics; and accordingly the tides are there greatest, and they diminish as we approach either pole. It is further to be remarked, that the moon does not anywhere draw up the tides immediately. Three hours elapse before the waters are raised, in consequence of the law of inertia, or a disposition which every body has to continue in the condition of rest or motion in which it happens to be placed. This stubbornness to resist the moon's influence is only overcome by a three hours' action upon the waters; and thus the tidal wave is always three hours behind the moon in its passage. In some of the firths or arms of the sea on the east coast of Scotland, it has been occasionally noticed that there have been four high-waters in the twenty-four hours. These, however, are not simple tides. The double risings are caused by the irregular passage of the tidal wave from the Atlantic round the north and south points of the island of Great Britain. When that portion of the wave which proceeds by the south reaches the east coast sooner than that by the north, or *vice versâ*, there will be two risings of the water instead of one. Moreover, in consequence of all the great seas and oceans forming, as we have seen, only one sheet of water variously distributed, the ebb and flow in each depend not on its own proper tide, but are the result of the combination of that tide with currents mingling with it from tides of other seas—a result depending upon inequalities of sea-bottom, the configuration of its coasts, their inclination under water, the size and direction of the channel which connects it with other seas, and occasionally upon winds and currents which are not tidal. So much do these circumstances affect the astronomical or *primary* tidal wave, that while it rises in the expanse of the Pacific to one or two feet only, the *derived* wave often rises in confined or obstructed seas to elevations of thirty, forty, or even seventy feet! This circumstance has given rise to the determination of *cotidal* lines, or lines which mark the contemporaneous position of the various points of the great wave which carries high-water from shore to shore. Inland expanses of water, like the Baltic, Mediterranean, and Caspian Seas, and the lakes of North America, have no perceptible tides.

Besides being affected by the regular motion of the tides, the ocean is pervaded by a system of *currents*, mostly constant, which has been compared to the circulation of the blood. These currents play a most important part in modifying the climates of different regions; the subject is also full of practical interest for navigation, and the chief states of Europe and America have agreed to co-operate for its due investigation. As respects the causes of oceanic currents, much remains to be cleared up; but some of the leading causes seem well established. The great disturber of the equilibrium of the ocean is the heat of the sun, so unequally distributed over the earth's surface. This acts in various ways. In one region the waters are expanded by heat, and rendered light; while in another they are condensed by cold, and made heavy. Over one tract, a hot thirsty wind scoops up in a few days a foot deep of water from the surface and precipitates it in one day perhaps over another tract. And wherever evaporation exceeds the fall of rain, there the water becomes salter, and therefore heavier, than that of the ocean generally. From the operation of these causes, we should expect a regular system of currents between the tropical regions and the poles, the lighter water flowing one way on the surface, the heavier below, and in the opposite direction; and such on the whole is found in fact to be the case. Motion once thus begun, however, is differently modified in each locality by the shape of the coasts, by prevalent winds, and other circumstances. But one cause which modifies all currents that tend either north or south, is the daily rotation of the earth. At the equator, any spot on the surface is moving eastward at the rate of 1000 miles an hour; at 60° north latitude, the velocity is only one half. Thus, the water of a current starting from the equator northwards, is constantly coming to places where the bottom under it has less and less eastward velocity. But, by the law of inertia, the water tends to retain the same velocity eastward with which it started, and thus it moves to the east of north—shooting ahead, as it were, of the bottom over which it is flowing, as a rider does whose horse slackens his pace. The contrary happens to a stream flowing from north to south. In this case, the eastward motion or motal inertia of the water is too slow for the parts of the bottom to which it successively comes; the bottom slips in a manner from under it, and it falls to west of south. This, in combination with the action of opposing coasts, accounts for the circular sweep which many of the currents make, returning partly into themselves.

The mightiest and best known of all oceanic currents is the Gulf Stream. 'There is,' says Lieutenant Maury, in his *Physical Geography of the Sea*, 'a river in the ocean. In the severest droughts it never fails, and in the mightiest floods it never overflows. Its banks and its bottom are of cold water, while its current is of warm. The Gulf of Mexico is its fountain, and its mouth is in the arctic seas. There is in the world no such majestic flow of waters.' Issuing through the straits or Gulf of Florida, between Florida and the Bahamas, it proceeds northward nearly parallel to the American coast, to the 35th degree of latitude; then bends gradually eastward, passing over the southern extremity of the Bank of Newfoundland, gradually expanding in breadth, and becoming shallower. Part of its water seems to turn southwards by the Azores; but the great body, according to Maury,

proceeds towards the British Islands, whose shores are bathed by it, and finds its way between Iceland and Scandinavia, into the arctic basin of Spitzbergen. The velocity of this current is about four miles an hour when it issues from the strait, but gradually diminishes. The temperature of the stream when it starts is 86°, and even after travelling 3000 miles to the north, as high as the Banks, there is a difference, in a winter day, between its water and that of the surrounding ocean, of 20° or 30°. It thus carries the warmth of summer into the midst of winter, and occasions the fogs that are so frequent in its northern course. Proofs of its reaching the west of Europe are seen in the drift-wood, seeds, and fruits from the West Indies frequently cast ashore on the west coasts of Ireland, the Hebrides, and Norway. But more important is the effect it produces on the climate of those countries. 'It spreads itself out for thousands of leagues over the cold waters around, and covers the ocean with a mantle of warmth that serves so much to mitigate in Europe the rigours of winter. It is the influence of this stream upon climate that makes Erin the "Emerald Isle of the Sea," and that clothes the shores of Albion in evergreen robes; while in the same latitude, on the opposite side of the Atlantic, the coasts of Labrador are fast bound in fetters of ice.'

Besides the Gulf Stream, a great *equatorial current* flows in the Atlantic from the west coast of Africa to the opposite coast of Brazil, where it is divided into two—one proceeding south along the coast; the other turning north, and entering the Caribbean Sea, where it helps to feed the Gulf Stream. A part of the waters of the Gulf Stream are deflected southward along the west of Europe, apparently to join this equatorial current; and thus there is formed a great whirl. In the middle of the vortex, westward from the Canaries, an immense tract of the ocean is covered with sea-weed (*fucus natans*), in many places so closely that it seems to the eye substantial enough to walk upon. This is the Sargasso Sea of the Portuguese.

The currents of the Pacific Ocean are little known; but the Indian Ocean, exposed to a tropical sun and hemmed in on the north, sends out several large currents of warm water. One is the Mozambique current; another escapes through the Straits of Malacca, and flows past China and Japan into the Pacific, making for the north-west coast of America. This current resembles in many respects the Gulf Stream.

Two currents of equal force, but of different directions, meeting in a narrow passage or gut, will cause a *whirlpool*, a phenomenon which has ignorantly been said to be produced by subterranean rivers, gulfs, chasms, &c., but essentially is only an eddy. Charybdis, in the Straits of Sicily, and the Maëlstrom, on the coast of Norway, are eddies of this kind, alternately absorbing and casting up again whatever approaches them.

Being an elastic and mobile fluid, water is readily acted upon by winds; and thus *waves* are produced, varying in height and velocity according to the force and continuity of the wind, extent of uninterrupted surface, depth of the ocean, contending currents, and the like. 'The common cause of waves,' says Dr Arnott, 'is the friction of the wind upon the surface of the water. Little ridges or elevations first appear, which, by continuance of the force, gradually increase until they become the rolling mountains seen where the winds sweep over a great extent of water. In rounding the Cape of Good Hope, waves are met with, or rather a swell, so vast, that a few ridges and a few depressions occupy the extent of a mile. But these are not so dangerous to ships as a *shorter* sea, as it is termed, with more perpendicular waves. The slope in the former is so gentle, that the rising and falling are scarcely felt; while the latter, by the sudden tossing of the vessel, is often destructive. When a ship is sailing before the wind, and riding over the *long swell*, she advances as if by leaps; for while each wave passes, she is first descending headlong on its front, acquiring a velocity so wild, that she can scarcely be steered; and soon after, when the wave has glided under her, she is climbing on its back, and her motion is slackened almost to rest before the following wave arrives. The velocity of waves has relation to their magnitude. The large waves just spoken of proceed at the rate of from thirty to forty miles an hour. It is a vulgar belief that the water itself advances with the speed of the wave; but in fact the *form* only advances, while the *substance*, except a little spray above, remains rising and falling in the same place with the regularity of a pendulum. A wave of water, in this respect, is exactly imitated by the wave running along a stretched rope when one end is shaken; or by the mimic waves of our theatres, which are generally undulations of long pieces of carpet, moved by attendants. But when a wave reaches a shallow bank or beach, the water becomes really progressive; for then, as it cannot sink directly downwards, it falls over and forwards, seeking the level.' Sailors and others speak of waves running 'mountains high;' but it is questionable if, even in the dreaded Bay of Biscay, they ever attain an altitude of thirty feet, measuring from the trough of the sea to the crest of the succeeding wave.

LAKES AND RIVERS.

Lakes are inland bodies of water not connected with the ocean or any of its branches: they are generally fresh, but are occasionally brackish, or even decidedly salt. They are classified according as they are fresh or saline, and according to the manner in which they receive and discharge their waters—namely, those that both receive and discharge running water; those that receive waters, but have no visible outlet, as the Caspian Sea; those which receive no running water (being fed by springs), but have an outlet; and such as neither receive nor discharge running water. Lakes are distributed over the globe according to the inequalities of surface; and all tend to annihilation, partly by silting up their basins, and partly by deepening their outlets, thereby effecting an entire drainage of their waters. By far the most gigantic are those of North America—such as Superior, Huron, Michigan, Erie, and Ontario, which respectively occupy 35,000, 20,000, 16,000, 10,000, and 7200 square miles. Next in order are the lakes of Asia, of which the largest are Aral and Baikal; the surface of the former is estimated at 23,000, and the latter at 15,000 square miles. Of the African lakes we have no definite information; but Europe can boast of a vast number, which, though generally small, give beauty and diversity to her landscapes. Those of Ladoga and Onega, in Russia, are the largest; the former having a surface of 6330, and the latter of 3280 square miles. A comparative estimate of the extent of these vast sheets may be formed, when we mention that the area of Lake Geneva does not exceed 340 square miles.

Lakes subserve important purposes in the economy of nature. They serve as reservoirs for the waters which rivers would too speedily carry away from the land; they are the tanks, as it were, in which the impurities of streams subside; they refresh and enliven the landscape; and as they all tend to silt up their own sites, these sites become in time tracts of fertile alluvium, and such has been the origin of some of our finest plains. They are also the scenes of extensive and varied vital operations. The plants which spring from their bottoms, or flourish by their margins, differ widely from true terrestrial and maritime vegetation; while the animals which people their waters exhibit peculiarities not less distinct and characteristic.

Rivers, streams, springs—whether flowing with a volume several miles in breadth, or trickling in a tiny rill which a child's hand might obstruct—constitute a class of the most valuable agencies in the physical history of our globe. They are the irrigators of its surface, adding alike to the beauty of the landscape and the

fertility of the soil; they carry off impurities and every sort of waste débris, to be deposited in the ocean as the strata of future continents; and when of sufficient volume, they form the most available of all channels of communication with the interior of continents. Man has ever located himself by their banks—using their waters for his domestic purposes, making their bosoms the highway of his commerce, and applying the force of their currents to the abridgment of his toil. They have ever been things of vitality and beauty to the poet, silent monitors to the moralist, and agents of comfort and civilisation to all mankind. The manner of their origin is this: The sun's heat, acting upon the ocean and other exposed surfaces of water, converts that element into vapour; this vapour, invisible, and of less specific gravity than the atmosphere, ascends, and forms clouds, mists, &c.; and when condensed by cold or other agency, as described under METEOROLOGY, falls by its specific gravity to the surface in the form of dew, rain, hail, and snow. Falling on the surface indiscriminately, these percolate the soil, find their way through the rents, fissures, and pores of the rocky strata, and ultimately escape at some lower level in the form of *springs*. Some of these springs are perennial, others temporary or intermittent: some are limpid, and almost absolutely pure; others are impregnated with metallic, earthy, and saline ingredients, according to the nature of the strata through which they have percolated: some are cold, others tepid; while many issue, with bubbling and steam, near the ordinary boiling-point of water. Springs, naturally tending to lower levels, unite and form *streams;* and these, again, falling still lower, conjoin in valleys, and form *rivers*—creating in their course rapids, cataracts, and water-falls, ravines and dells, lakes, swamps, and marshes, alluvial plains, and low terminating deltas. The valley in which a river flows is usually termed its *basin;* and its *drainage* is that portion of country drained by its streams or tributaries. To compare merely the lengths of rivers is far from conveying a correct idea either of their physical or economical importance; the extent of their basins is an equally important item. The following is a comparative view of the length and drainage of some of the principal rivers on the globe, headed by the Thames as a standard of comparison. The measurements are stated in geographical miles of sixty to a degree. The geographical mile contains 6086 feet, and the British statute mile 5280 feet.

PRINCIPAL RIVERS.		Length in Miles (geog.).	Drainage in Square Miles (geog.).

CLIMATOLOGY.

The climatology of the globe relates to the degree of heat and cold to which its respective countries are subject, the dryness and moisture of the air, and its salubrity or insalubrity as influenced by these and other causes. As yet the minutiæ of climate are but imperfectly determined; the following general causes, however, have been sufficiently ascertained:—1. The action of the sun upon the soil and atmosphere; 2. The internal heat of the globe; 3. The height of the place above the sea; 4. The general exposure of the region; 5. The direction of its mountains relatively to the cardinal points; 6. The neighbourhood of the sea, and its relative position; 7. The geological character of the soil; 8. The degree of cultivation which it has received, and the density of the population collected upon it; and 9. The prevalent winds. These causes, acting together or separately, determine the character of a climate as moist and warm, moist and cold, dry and warm, dry and cold, &c.; and this climatic character is the main influence which determines the nature and amount of vegetable and animal development.

The torrid zone has two seasons—the wet and the dry. The latter is considered as the summer, and the former as the winter of the regions within this zone; but they are in direct opposition to the astronomical seasons, as the rains follow the sun. In some districts, there are two rainy and two dry seasons every year. In the temperate zones, the year is divided into the four seasons whose changes are so agreeable and salubrious. This regular succession of the annual changes, however, can hardly be considered as extending further than from 35° to 60° of latitude. In the frigid zones, two seasons only are known—a long and severe winter, and a short but fervid summer. This abrupt and harsh transition is occasioned by the great length of the day in summer, when the sun never sets, and by the total absence of that luminary in winter. The decrease of heat as we recede from the equator is greater in the southern than in the northern hemisphere. According to Humboldt, continents and large islands, as a general rule, are warmer on their western than on their eastern sides. The extremes of temperature are more felt in large inland tracts than in islands and situations near the coast. The sea absorbs and radiates heat more slowly than the land; and thus after the land has lost its warmth, the ocean is radiating its tempering influences. For these reasons, climatologists have found it necessary to construct *isothermal lines* round the globe; that is, lines along which the annual mean temperature is the same. Again, places which have the same mean annual temperature vary considerably in their mean summer and winter temperature; hence *isochimenal* lines, or lines of equal winter temperature, and *isotheral* lines, or those which shew equal summer over points upon different isothermal curves. Another set of lines or curves, called *isogeothermal*, connect points where the temperature of the soil is equal at or beneath the surface.

Since the temperature of the atmosphere diminishes with the altitude, a limit must be reached where water will remain in perpetual congelation, independent of all seasonal influences. This limit is called the *snow-line*, and is found at various heights, according to latitude, proximity to the sea, and other causes, which affect the general climate of the region. In the Himalaya and Andes, it is found at an elevation of about 17,000 feet; in the Swiss Alps, at 8500 feet; and in the Scandinavian range, at 3500 feet. Generally in those countries which are near the equator, the snow-line is found about 16,000 feet, or three miles above the sea-level; about the 45th parallel in either hemisphere, it occurs at an elevation of 9000 feet; under 60° of latitude, at 5000 feet or thereby; under 70° of latitude, at 1000 feet; and under 80°, the snow-line comes down to the mean sea-level, for countries which are 10° distant from the poles are covered with snow all the year round. From snow and glacier clad mountains cold breezes rush down to cool the adjacent plains; and similar winds blow from the arctic to the tropical regions. Indeed, wherever the air of one region becomes heated or rarefied, the colder and heavier air of the surrounding regions will rush in to restore the balance. Such is the cause of all aërial currents, and in particular of those blowing within the

25th degree of latitude on either side the equator, known as the *trade-winds*. *Monsoons*, the *simoom*, *harmattan*, *sirocco*, and other local winds, *sea and land breezes*, and in fact every species of aërial current, may be traced to similar causes. (See METEOROLOGY.)

The amount of *rain* which falls on the earth's surface is exceedingly varied, ranging from twenty or thirty inches to several feet per annum, and that within comparatively short distances. On the east coast of Great Britain, the average fall is about twenty-four inches; in some parts of the mountains of Cumberland, it reaches 100 inches. The greatest amount of rain recorded is among the Khasia Mountains, to the north-east of Calcutta; at the Churra station, 500 inches have been measured in seven months, and the single month of August has given twenty-two feet. But the moisture of a climate does not wholly depend upon the amount of rain registered by a rain-gauge; for some climates are humid, and yet not rainy; others dry, and yet subject to periodical torrents. These torrents give rise to inundations; hence the peculiar seasonal floodings of such rivers as the Nile and Ganges. The mean annual fall of rain on the entire surface of the earth is estimated at five feet.

DISTRIBUTION OF PLANTS AND ANIMALS.

The *life* of the globe—that is, its vegetable and animal productions—constitutes its most important and exalted feature as a creation. All the varied materials of which it is composed, all the complicated actions, reactions, and mutations to which they are subject, are humble phenomena compared with the production of the lowliest organism. This life is everywhere: the waters teem with it, the dry land from pole to pole is clad with it; nay, there is life within life, and perhaps there exists not a single plant or animal but becomes in turn an abode for others of more diminutive dimensions. Speculations as to the origin and generic classification of vegetable and animal life belong not to our subject. Geography views them simply as they exist, and endeavours to determine the laws which regulate their distribution.

Vegetables are regulated in their terrestrial distribution by conditions of soil, heat, moisture, light, height of situation, and various other causes; *in the waters*, by depth, heat, light, nature of bottom, and the presence of mineral and saline ingredients. Were it not for these causes, there is no reason why the tribes and genera of one region should not be identical with those of another—why the palms of India should not flourish alongside the oaks of England, the oaks of England with the pines of Norway, or these again with the dwarf birches of the arctic regions. As it is, the tropics have genera unknown to the temperate zone, and every advance poleward brings us in contact with new and peculiar species. Temperature in this case seems to be the grand regulating condition; and as this is effected by elevation, as well as by increase of latitude, we find the mountain-ranges near the equator presenting all the features of a tropical, temperate, and even arctic vegetation. Thus palms and plantains may luxuriate at their bases; then appear oranges and limes; next succeed fields of maize and wheat; and still higher, commences the series of plants peculiar to temperate regions. In temperate latitudes, though the variety of vegetation be less, similar phenomena present themselves. Besides these great climatic effects, there are others depending on soil, moisture, light, &c., which, though limited, are not less imperative. Thus, the southern slope of a hill is generally clothed with species distinct from those on the north; a limestone district presents a carpet of vegetation widely different from that of the clayey moorland: some tribes flourish in the moist valley, which would die on the open plain; some tribes thrive in the marsh, others on the dry upland; some luxuriate under the influence of the sea-spray, which would be instant destruction to others. But whilst most species are subject to these laws, there exists in the constitution of many a certain degree of elasticity which admits of their adaptation to a wider range—a beneficent arrangement, which permits man to extend through cultivation those grains and fruits upon which his subsistence so essentially depends. (For further and more minute information respecting the laws which regulate the dispersion and distribution of plants, see VEGETABLE PHYSIOLOGY.)

The animals which people the globe are subjected to somewhat similar laws of distribution. Some are strictly tropical, others confined to the temperate zone; while not a few are destined to find their subsistence wholly within the polar circles. Besides this general distribution, we find a more particular restriction to certain continents and tracts where peculiarities of soil, climate, and food seem to be the governing conditions. Thus, the elephant roams only in India, Burmah, and Africa; the ostrich in Africa; the rhea in the pampas of South America; the kangaroo in New Holland; the reindeer within the arctic circle; the polar bear amid the snows of Greenland and Labrador; and so on, as will be more minutely shewn under ZOOLOGY. Similar laws are impressed on the life of the ocean. The 'right' whale, as it is termed, of the northern hemisphere, is a different animal from that of the southern; for 'the tropical regions of the ocean are to him as a sea of fire, through which he cannot pass, and into which he never enters;' while the sperm whale delights in warm water. The herring finds its chosen habitat in the Northern Sea; the oyster clings to a peculiar bottom, at a certain depth; the cod inhabits the same banks and shoals for ages; and a few fathoms of greater or less depth would be more fatal to many species of shell-fish than the dredge of the fisherman. As on plants, so on animals, altitude exerts a very decided influence; and we do not exaggerate when we affirm that a lofty mountain-range presents a more impassable barrier to vital distribution than the widest expanse of ocean. Though presenting a close analogy in the manner of their distribution, plants and animals differ in this respect, that many tribes of the latter—birds, fishes, and mammalia—make periodical migrations of vast extent; food and proper breeding-places being the objects of their search. These migrations must not be confounded with that adaptability of constitution which fits the horse, the dog, the ox, the sheep, the pig, and other domestic animals, to be the companions and supports of man in his onward possession of the globe. The one is but a change of place in search of food, under a congenial temperature; the other amounts to a constitutional change, irrespective of climatic influence.

Man, of all animals, has the widest geographical distribution. This he enjoys not only from the greater adaptability of his constitution, but from that superior intelligence which enables him to counteract the effects of climate by clothing, houses, fire, and the storing of provisions. It may be justly affirmed, therefore, that there is no region where man may not exist and carry on the purposes of life in a higher or lower degree of civilisation. Though generally regarded as a single species of a single genus, naturalists have divided mankind into several varieties, according to their more prominent physical features; and ethnologists, extending the subject according to minor features, language, and so forth, have subdivided these varieties into branches, types, tribes, and families. That the external conditions to which man, like all other animals, is subjected, may in the course of ages have stamped the inhabitants of certain regions with certain physical characteristics, is nothing more than what may be expected; but that every little difference of dialect, every tint of skin or colour of hair, every mould of nose or contour of skull, is warrant sufficient for a new subdivision, is an absurdity not to be tolerated. An account of the principal varieties will be given in a separate sheet devoted to ETHNOLOGY.

VEGETABLE PHYSIOLOGY.

THE science which embraces the study and investigation of the vegetable kingdom, is known by the name of BOTANY, from the Greek word *Botané*, a plant. That department of the subject which explains the organisation and vital functions of plants, we call *Vegetable Physiology;* and that which recognises their arrangement into orders, tribes, genera, and species, according to their respective forms and qualities, *Systematic Botany*. The one relates to functions which are common to all vegetables, the other takes notice only of those structural peculiarities which serve to distinguish one species from another, and to enable the botanist to form these into natural and artificial groups. It is to the former of these departments that we now direct the attention of the reader.

GENERAL ECONOMY OF VEGETATION.

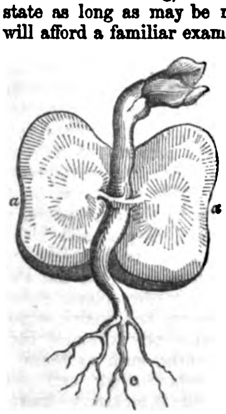
Nature and Functions of Plants.—Minerals, plants, and animals are all formed by the chemical combination of certain elementary substances. In minerals, these elements combine by the force of chemical affinity only, but in plants and animals they are held in combination by vital action. Of the nature of life, or the vital principle, science does not attempt to explain the cause, but restricts itself to a mere exposition of its phenomena. Vitality enables plants and animals to absorb and assimilate food, consisting of the elements necessary for their increase, and also to reproduce beings of their own kind; these functions are performed by means of certain organs: hence the origin of the term *organised*, which is now, however, employed to indicate the possession of vital tissues. Animals feed partly on other animals, and partly on plants; and plants feed partly on organic matter when decomposed, and partly on inorganic. Thus mineral substances, by the beautiful economy of nature, contribute towards the support of animals through the medium of vegetation, and these again, by their death and decay, return their elements to the inorganic world.

The simplest forms of life are observable in certain plants and animals, whose economy is limited to the absorption and assimilation of nutriment, and the power of reproduction; and the difference between these inferior forms is so trifling, that in them the animal and vegetable kingdoms seem to pass into each other. Thus certain tribes of animals, and some kinds of algæ, are so very nearly allied, both in appearance and habits, that they can scarcely be distinguished from each other scientifically; and indeed the same object has been occasionally classed as a plant by one naturalist, and as an animal by another. The absolute differences between plants and animals are indeed difficult to define, when they are to be applied to all plants and to all animals. Many of the infusoria of Ehrenberg, which have been described as animals, are now regarded as belonging to the vegetable kingdom; while a large number of organisms exist whose place in the system is still undetermined. In many cases, form and structure afford no decisive characters whereby we may separate the two kingdoms from each other; while phenomena usually regarded as pertaining to the animal kingdom are prevalent in the lower forms of plants, and indicate that no reliance can be placed upon their mode of life. In like manner, the chemical distinctions upon which much dependence has hitherto been placed, give way before increased knowledge; for cellulose and starch, long considered as peculiarly vegetable products, are now known to occur in animal structures. The locomotive power of many of the lower algæ is greater than that of many animal organisms; and even the spores, or seeds, of algæ of more complex organisation move about, when freed from their parent, with an activity which appears truly animal, by means of the cilia with which they are provided. When the spore finds a suitable resting-place, its movements cease; and having thus exchanged its animal-like mode of life for one of a less erratic character, it becomes developed into a beautiful alga in all respects resembling its parent. The constant recurrence of this active period in the alga's life is one of the best indications that mere power of locomotion cannot be founded upon as a proof of the animal nature of any organism. It may here be stated, however, that in the higher plants and animals, the whole plan of structure and vital phenomena are diverse in the two classes of beings. Even in the highest plants, all the processes of growth and reproduction are performed simply by cell-development; we have no circulatory and no nervous system, no power of sense or of voluntary action. The two classes, plants and animals, seem, as it were, to start from a common point at the base, the inferior forms bearing a certain similarity in structure and functions, which gradually disappears as we ascend in the scale of development.

Plants derive their food partly from the soil and partly from the air; and whatever they take must either be reduced to a liquid or to a gaseous state. The ultimate elements of which plants are composed are—carbon, oxygen, hydrogen, and nitrogen. Of these, carbon, which is a solid substance, is the principal; and as it is insoluble in water, it must be combined with oxygen, so as to form *carbonic acid gas*, before it can be taken up by plants. Oxygen is the next in abundance, and it is absorbed principally when combined with nitrogen, in the form of atmospheric air. Hydrogen is not found in a free state in the atmosphere, and therefore it can only be taken up by plants when combined with oxygen, in the form of water, or with nitrogen, as ammonia, in which last form it exists in animal manure. Nitrogen, though found in very small quantities in plants, is an important element, as it constitutes the principal ingredient in the *gluten*, which is the most nutritive part of corn and other seeds, and which is essential to the germination and nourishment of young seedling plants. Nitrogen also appears to be a principal agent in the production of colour in leaves and flowers, especially when they first expand. As oxygen is imbibed by plants in combination with all the other elements of which they are composed, it is not surprising that the plant takes up more of this gas than it requires; and, consequently, it has been furnished with a remarkable apparatus in the leaves, to enable it to decompose the carbonic acid and other gases which it has absorbed, and to part with the superfluous oxygen. Plants are thus found to improve the air by the removal of carbonic acid, which is injurious to animal life, and by the restoration of oxygen, which is favourable to it; and so to maintain a necessary equilibrium in the atmosphere, as animals are continually absorbing oxygen, and giving out carbonic acid. In hot swampy countries, however, where vegetation is extremely rapid, and the soil surcharged with decaying vegetable matter, plants absorb more carbonic acid than they want, and under certain circumstances give out the superfluity through their leaves; hence warm moist climates, such as those of some of the West India Islands, though extremely favourable to vegetation, are highly injurious to human life. Light being essential to the decomposition of

carbonic acid gas in the leaves, oxygen is not exhaled by plants during the night; but, on the contrary, a small quantity of carbonic acid gas escapes, and oxygen is absorbed. These processes have been called the *respiration of plants;* but they are very different from the respiration of animals. When the soil abounds in carbonic acid gas and in moisture, the roots of a plant must continue constantly absorbing that moisture mixed with the carbonic acid; and this carbonic acid rising to the leaves, escapes in its original state, when there is no light to decompose it. The absorption of oxygen is a chemical process, which appears to go on whenever the process of assimilation has ceased—in dead plants as well as in living ones. When leaves have ceased to act in decomposing carbonic acid, and assimilating or fixing the carbon in autumn, oxygen is absorbed so rapidly as to change their colour to some shade of red; fruit, when fully swelled, ceases to assimilate carbon, and becomes intensely acid by the absorption of oxygen; and, finally, the decay of all vegetable texture is hastened by the absorption of the same element. Thus, as the assimilation of carbon ceases during the night, oxygen is absorbed at that period in quantities that vary according to the nature of the plant; those plants which have acid or highly flavoured juices absorbing most. Baron Liebig tells us that the tasteless leaves of the American aloe (Agave), if kept in the dark twenty-four hours, absorb only 0·3 of their volume of oxygen in that time; while the leaves of the spruce fir, which contain volatile and resinous oils, absorb ten times—those of the common oak, which abound in tannin, fourteen times—and those of the balsam poplar, twenty-one times, as much. The chemical action of oxygen on vegetation is strikingly exemplified in the leaves of a species of navel-wort, which are said to be acid in the morning, tasteless at noon, and bitter at night—the acidity being caused by the accumulation of oxygen during the night, the noonday insipidity by the mixture of the oxygen with hydrogen, and the nocturnal bitter flavour by an excess of hydrogen.

Development of Vegetable Life.—This depends upon the concurrence of certain agents, the principal of which are—heat, air, moisture, light, and soil. No seed can germinate without the concurrence of the three agents of heat, air, and moisture; but in the *growth* of most plants, the agency of soil and light is also necessary. Every perfect seed contains the germ or embryo of a new plant of the same kind as the parent, and a portion of concentrated carbon and nitrogen, in the form of starch and gluten, laid up to serve as nutriment for the young plant, till its organs are sufficiently developed to enable it to seek food for itself. This nutrient matter is either contained in the tissues of the embryo itself, or laid up beside it in the seed, in the form of separate albumen. The seed is generally furnished with a hardened covering, in order to preserve it in an inert state as long as may be necessary. The common bean will afford a familiar example of the process of germination.



As soon as it is put into the ground, it is acted upon by the influence of heat and moisture, which distend its tissues, so as to burst the external integument. The agency of the air is next required to combine with the store of nutriment laid up in the seed, and to fit it for the purposes of vegetation. The first organ which expands in the embryo of a young plant is the radicle *c;* and nature has provided a small opening in the covering of a seed, towards which the point of the root is always turned, in order that it may be protruded without injuring its soft and delicate texture. The radicle takes up water and air, and transmits the liquid thus formed to the other tissues. The nutritive substances laid up in the cotyledons (*a a*) of the seed become quite changed during the process of germination. The starch, which is insoluble in water, is rendered soluble by the action of a peculiar substance called *diastase,* derived from the gluten. This substance has so powerful an effect upon the starch as to render it instantly soluble in the sap, and thus nutriment is gradually prepared for the use of the infant plant. As the sap ascends, it becomes sweet, the starch becoming changed into sugar, and this sugar, again, into woody fibre as the tip of the plant emerges into light. When the store of starch and gluten has been exhausted, the plant is able to subsist by its own assimilating powers, at the expense of the air and the soil.

Heat, though essential to germination, is injurious, unless it be combined with moisture. A high degree of dry heat will parch seeds, and destroy their vitality; hence, when they are to be kept for food, it is not unusual to dry them in an oven, to prevent them from germinating. When combined with moisture, a very high temperature is not injurious to many kinds of plants, especially those of low organisation; for example, various species of Oscillatoria inhabit the hot springs of Italy and the hot-water pools around the geysers in Iceland; while, on the other hand, certain lichens and mosses grow in the region of perpetual snow, where the temperature seldom rises to 32° Fahrenheit. Warmth is not only necessary for the germination of the seed, but also for the growth and after-development of the plant. In flowering plants the sap will not rise without a certain degree of heat; and it is well known that frost stops its current. Cold will also check the development of the flowers and fruit, and even of the leaves, and will prevent the full flavour being attained by the fruit. The secretions of plants are diminished by cold. The fruits of the walnut and the beech produce oil in the south of Europe, but not in Britain; and the leaves of the mulberry grown in this country will not afford the same quantity of caoutchouc to the silk-worm as in France and Italy.

Moisture must be combined with heat and air to render it useful to vegetation. An excess of moisture without heat, and combined with air, induces decay in seeds, instead of exciting them to germinate; and an excess of moisture is injurious even to growing plants, as it destroys the delicate tissue of the spongioles of their roots. When trees are grown in situations where they have abundance of heat and moisture, but where the roots are beyond the reach of air, they have a tendency to produce leaves instead of fruit and seeds, and all their secretions are weakened. On the other hand, too little moisture prevents the leaves and fruit from attaining their proper size and form.

Air is essential both to the germination of the seed and the development of the plant. Without oxygen from the atmosphere, the carbon laid up in the seed cannot be made available for the use of the infant plant, as carbon in its concentrated state is insoluble in water, and requires to be combined with oxygen to convert it into carbonic acid gas. In like manner, air is essential through all the processes of vegetation; no wood can be formed, no seed ripened, and no secretions produced, without abundance of carbon; and this cannot enter the plant, even from the soil, without a constant supply of oxygen from the air. The greater part of the carbon in plants is indeed derived directly from the air by the leaves, in the shape of carbonic acid gas—a minute quantity of which is always found in combination with the atmosphere.

Light is not required for the germination of seeds, but it is essential to the development of plants, as it occasions the decomposition of the carbonic acid contained in the parts exposed to its influence; without which the plant

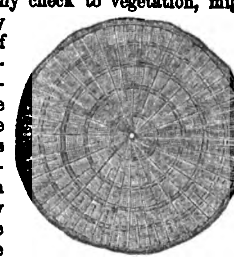
could not assimilate the carbon. Colour also appears to depend partly on light. Plants grown in darkness are of a sickly aspect, and are said to be *etiolated*, or blanched.

The soil serves not only as a bed for plants to grow in, but also contributes to their nourishment. In addition to the elements of which they are principally composed, there is always found in their substance a small quantity of inorganic matter, which differs according to the nature of the plant, and which appears to be derived solely from the soil. Plants require different kinds of inorganic food, according to their nature, and appear to possess the power of selection, as they only take the kind they need, though it may form but a very small portion of the soil in which they grow. Thus it is evident that any particular crop must in time exhaust the soil in which it grows of the requisite inorganic matters, unless they should be renewed by the addition of what are called mineral manures (see AGRICULTURE); and it is also clear that crops requiring another kind of earth may succeed in the same soil after it has become unproductive for the first kind of crop. This, according to modern doctrines, explains the necessity which is known to exist for what is called *the rotation of crops*—that is, for letting crops of a different nature succeed each other in fields and gardens. The necessity for this rotation was supposed by Decandolle and others to arise from plants poisoning the soil with the excrementitious matter which they were supposed to eject by their roots; but, while this hypothesis was believed, it appeared difficult to account for the well-known fact, that the same crops could be grown perfectly well in any soil for an indefinite number of years, provided that soil were frequently and properly manured; that is, supplied afresh with the ingredients of which it had been exhausted by the plants. As to the matter which is discharged from the roots, it is not definitely known to exercise any deleterious effect upon the same kind of crop in the manner Decandolle supposed.

Nature, when unassisted, invariably makes an effort to change the crops of plants. When a forest in North America is burnt down by accidental fires in the summer season, trees of quite a different kind spring up from long concealed seeds, in place of those which have been destroyed. When, in ordinary circumstances, one kind of plant has exhausted the soil in its neighbourhood, it pushes its roots to as great a distance as possible in quest of food, and there sends up shoots, while a new race of plants grows upon the spot which it has vacated. In these, as in a thousand other circumstances, we find that one of nature's great primary laws is that of perpetual change—an alteration from one condition and appearance to another, in endless succession and variety. In the artificial cropping of the ground, the farmer, for his own sake, is impelled to take a lesson from nature, and to study what species of plants he can most advantageously produce in succession from his fields. (See AGRICULTURE.)

Term of Vegetable Existence.—The longevity of plants differs according to their nature and the circumstances in which they are placed: thus herbaceous plants, the stems of which are succulent, not permanent and woody, are *annuals*—that grow only one season, and die as soon as they have ripened their seed—*biennials*, which generally last for two years—or *perennials*, which last for several years. Trees and shrubs, which have ligneous or woody stems, are destined to remain undecayed for years. The term *shrub* is applied to those woody plants which branch out from near the root, and seldom attain a great height; while *trees* have, generally speaking, only one stem or trunk proceeding from the root to a considerable height before it divides into branches. The length of time which trees live depends in a great measure on the situations in which they grow. If a tree which is a native of mountains be placed in a valley, it grows more rapidly, but the term of its existence is shortened, and its timber becomes softer. In like manner, if the tree of a valley be grown on a mountain, the term of its existence is lengthened, and its trunk is of slow growth and small dimensions; but it has not been ascertained that its timber is more durable on this account.

The age of trees was formerly calculated by their diameter, or by the number of concentric circles or layers in the trunk; but both these modes are now found to be fallacious. According to the first, it was supposed that if a tree attained the diameter of a foot in fifty years, fifty years should be counted for every foot it measured in diameter; and thus it was supposed that the great baobab-tree, found by Adanson on the banks of the Senegal, which measured nearly thirty feet in diameter, must have been about 6000 years old, or coeval with the world itself. It is now found, however, that the baobab, like all soft-wooded trees, grows rapidly, and attains an enormous diameter in less than a hundred years. The mode of counting by concentric circles only applies to exogenous trees, and even with them is very uncertain. A warm spring, which sets the sap early in motion, followed by weather cold enough to check vegetation, will give the appearance of two layers in one year, as the recommencement of vegetation will have the same appearance as a new layer in spring. In many trees, such as the oak, for example, a second growth often takes place after midsummer; so that even a third layer is occasionally formed in the course of six months. On the other hand, it is possible that a moist warm winter, by keeping the tree growing the whole year without any check to vegetation, might give the appearance of only one layer to the growth of two years. Notwithstanding these anomalies, practical men find counting the concentric circles of a tree the best mode which has yet been discovered of ascertaining its age, as in northern countries only one growth is made in the course of a year. The accompanying figure represents a section of an exogenous stem five years old, having the pith in the centre, a cylindrical layer for every year of the growth, and the bark on the outside.



DISTRIBUTION OF PLANTS.

The geographical arrangement of the vegetable world is influenced by conditions of soil, heat, moisture, light, altitude of situation, and various other causes; for, did they flourish independently of these conditions, then there were no reason why the vegetation of one part of the globe should differ from that of another. We know, however, that the flowers, shrubs, and trees which adorn the plains of India, are not the same with those which clothe the valleys of Britain; and that these, again, are totally different from the scanty vegetation of Iceland or Spitsbergen. Each species is, nevertheless, perfectly adapted to the conditions under which it exists, and finds in its *habitat*, or native situation, all the elements required for its growth. Obvious, however, as are the effects of these external conditions, the mode in which they operate is but imperfectly known.

In a state of domestication, however, many species exist in regions far beyond the limits of their original distribution. Our cultivated useful plants are of this kind; as, for example, the potato. This plant, which is a native of tropical America, flourishes luxuriantly, and is of the highest utility in Northern Europe; but this it does by a special adaptation. In South America, the warm climate enables it to propagate by the seed; hence in that region its tubers are small and insignificant; but in Europe, where the climate is unfavourable to the production of the plant from seed, it propagates by the tubers, which are consequently enlarged,

so as to contain a store of nutriment for the young plant, before its stem and leaves be sufficiently developed.

The habitats of plants—that is, the situations in which they naturally thrive best—are generally distinguished as follow:—*Marine*, when the plants float upon, or are immersed in, salt-water, such as sea-weeds; and *maritime*, when they grow by the sea-shore, or in places exposed to the influence of the sea-breeze. *Aquatic* is the general term for fresh-water habitats; and these may be *lacustrine*—that is, growing in lakes—*fluviatile*, in rivers—or *palustrine*, when in marshes or wet meadow-lands. Plants are also distinguished as growing in open pastures, in cultivated lands, woods, mountainous parts, and in caves, mines, and other underground excavations. The term *epiphyte* indicates that the species grows upon others, living or dead, without deriving from them the elements of nutrition; and *parasite*, that it adheres to their surface, enters their tissue, and directly extracts its nourishment. The range of habitat is that extent of the earth's surface over which a plant is distributed by nature. The terms maritime and alpine, for example, are general in their application, and refer to all plants which grow by the sea-side or on mountains; but the plants which flourish on the sea-shores of Great Britain are not the same with those on the coast of Africa; nor are these, again, identical with the maritime vegetation of Chili. The geographical range of any plant conveys a more special idea, and embraces only that particular tract over which the species extends. This range is circumscribed by conditions of temperature, light, and elevation above the sea, and does not, as might be supposed, depend very closely upon belts of longitude, by which temperature is generally indicated. Thus, nearly all the beautiful Pelargoniums and Mesembryanthemums which adorn our green-houses, are natives of a limited space near the Cape of Good Hope, as are also many of our most beautiful bulbs. The curious Stapelias, that smell so much like carrion, are found wild only in South Africa. The different kinds of Eucalyptus and Epacris are restricted to Australia. The Umbelliferous and Cruciferous plants spread across Europe and Asia; the Cacti are found in tropical America; and the Labiatæ and Caryophyllaceæ are seldom found beyond Europe. The peculiar ranges and centres of vegetation, as they are termed, cannot be sufficiently understood, however, without a knowledge of the different tribes and classes of plants, the consideration of which forms the subject of next paper—SYSTEMATIC BOTANY.

Soil exercises less influence on the distribution of plants than is usually ascribed to it, though there can be no doubt that on its power of absorbing and retaining heat and moisture much of the luxurious growth of vegetables depends. They will grow to some degree in almost any soil, as the bulkier ingredients—clay, lime, and sand—always predominate; but a proper proportion of these earths is necessary to perfect vegetation, and many plants will not continue healthy and propagate unless supplied with other elements, such as potash, soda, and various metallic salts. For this reason, the natural vegetation of a limestone country differs from that of a retentive clay; while the plants which cover all sandy downs are totally different in kind and character from those of the alluvial valley. Moisture, which is indispensable to the existence of vegetation, also exercises great influence in its natural distribution. The plant which roots in the parched sand is furnished with leaf-organs to absorb moisture from the atmosphere, and retain it; while in a wet situation these organs would become diseased, and rot away; so, in like manner, a marsh-plant, whose spongioles are its main organs of sustenance, would perish were it removed to an arid soil. The organic structure of such plants forms a limit to their distribution; and the same may be said of the Salicornia, Lepigonum, &c., which live only when exposed to the salt spray of the ocean.

Heat and light are perhaps the most manifest agents in the distribution of vegetable life. The luxurious growth of the tropical jungle is the direct result of warmth and moisture, just as the barrenness of Nova Zembla is the effect of piercing cold; yet both situations are inhabited by plants which enjoy the conditions peculiar to their existence. No conditions of mere soil, or light, or moisture, could make the palms, tree-ferns, and jungle-flowers of India flourish in Great Britain; so neither would our oaks or pines flourish in Iceland, unless we could provide for them that temperature and seasonal influence necessary to their healthy existence. Light, though it acts most powerfully on the colours and blossoms of plants, is in some measure an element in their geographical arrangement. The northern side of a hill may sometimes be as green, but it never will be so flowery as the southern exposure; and the attentive observer may detect new tribes on either side almost as soon as he has passed the summit. The more free the exposure, the more readily will most plants also blossom, and yield a rich fruit. So well is this understood in the grape-countries on the Rhine, that the right bank of that river, which faces the sun, is reckoned to be much more valuable than the left, and commands a higher price for its wines.

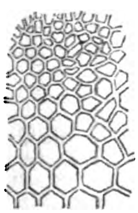
Altitude, or elevation above the ordinary sea-level, also exerts an obvious influence on the distribution of vegetable life: it is equivalent to removal from a tropical to a temperate region, or from temperate latitudes to the arctic circle. For every hundred feet of ascent, there is a proportional fall of the thermometer; so that, at the height of 5000 feet in the latitude of Britain, and 16,000 at the equator, we arrive at the region of perpetual snow; in other words, to heights as destitute of vegetation as the frozen zone. This intimate relation between altitude and decrease of temperature accounts for the fact, why the base of a mountain may be clothed with the vegetation of tropical India, the sides with that of temperate England, and the summit with the mosses and lichens of icy Labrador. 'We may begin the ascent of the Alps, for instance, in the midst of warm vineyards, and pass through a succession of oaks, sweet chestnuts, and beeches, till we gain the elevation of the more hardy pines and stunted birches, and tread on pastures fringed by borders of perpetual snow. At the elevation of 1950 feet, the vine disappears; and at 1000 feet higher, the sweet chestnuts cease to thrive; 1000 feet further, and the oak is unable to maintain itself; the birch ceases to grow at an elevation of 4680; and the spruce fir at the height of 5900 feet, beyond which no tree appears. The Rhododendron ferrugineum then covers immense tracts to the height of 7800 feet; and the herbaceous willow creeps 200 or 300 feet higher, accompanied by a few saxifrages, gentians, and grasses; while lichens and mosses struggle up to the imperishable barrier of eternal snow.'

The circumstances which facilitate the dispersion or migration of plants, are not unconnected with the causes which limit their geographical distribution. Many seeds drop from the parent stalk, spring up into new series of stems, which in turn give birth to another race of seeds, and these again to another circle of vegetation. Thus, any species of plant would spread from a common centre till arrested by the influences which limit its range of habitat; and this mode of dispersion no doubt occasionally occurs. In most plants, however, the seeds are small and light, and easily borne about by the winds: some are downy, and furnished with wings, while others are ejected from their carpels with considerable force. All these appendages and peculiarities are evidently intended to facilitate their dispersion, which is further assisted by rivers, lakes, and tidal currents, by the wool of animals, the droppings of birds, and the economical pursuits of man, whether accidental or intentional. The seeds are arrested in their progression by various causes: some are furnished with barbs and

hooks, which lay hold of objects; others become entangled amid herbage, the mud of rivers, or the softened soil of winter; while many, towards spring, are acted upon so as to emit an adhesive substance, or their fleshy pericarps melt down into the soil, carrying the embryo along with them.

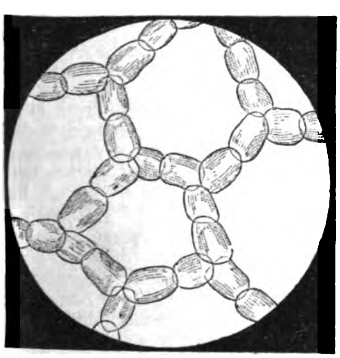
STRUCTURE OF PLANTS.

In order to explain the varied phenomena of plant-life, we must revert to the elementary tissues of which the various compound organs are composed. It is in these tissues that the processes of growth and multiplication, of individual development and of reproduction, can alone be accurately traced. Vegetable Histology limits itself to such investigations. If we cut a thin slice from the leaf or stem of a plant, and place it under the object-glass of a microscope, we shall find it to present the general appearance of a web or tissue, more or less of a honeycomb form, as represented in the wood-cut (*a*). If more carefully examined, it will be found that the apparent meshes of the net-work are not hollow spaces or perforations in a homogeneous mass or membrane, but that each has its own envelope, is, in fact, a minute bladder or vesicle, or elongated tube, as the case may be; and that the whole mass of tissue is formed by the aggregation of such vesicular or tubular bodies held together by means of an imperceptible layer of intercellular matter, which causes the contiguous cell-membranes to cohere. In the tissues of plants there is an infinite variety, both as regards the form and arrangement of their elementary bodies, the cells; but all may be reduced to three distinct types of structure, to one or other of which every modification can be referred. These are distinguished as the *cellular*, *woody*, and *vascular* tissues.

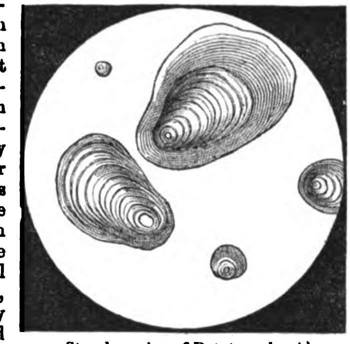


a, Cellular tissue.

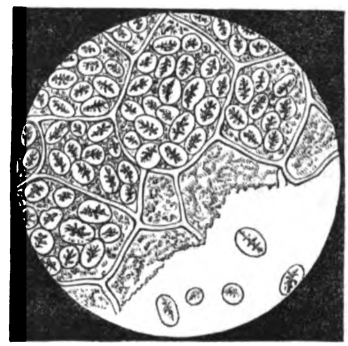
Cellular tissue may be said, in general terms, to form the soft and succulent parts of plants—as, for example, the pith of trees, the delicate central tissue of Papyrus, shewn in the adjoining figure (*b*), and the soft parts of our esculent vegetables and fruits. It is composed of minute bladders or vesicles, which are called *cells;* these are seldom so large as to be visible to the naked eye, but are readily seen under a compound microscope. They usually consist of a pellucid membrane, and are filled with fluid, in which float the cell-contents. These consist principally of the starch and chlorophyll granules; the latter, which are of a green colour, serving to give the usual green hue to vegetation. Starch is a very abundant substance in plant-cells, serving purposes of nutrition, and may be readily seen by placing under the microscope a thin slice of potato upon which a drop of tincture of iodine has fallen; this induces a beautiful blue colour in the starch-granule, and is a constant test for the occurrence of starch. Starch usually occurs in the form of minute grains, many of which are contained in each cell. Their form is often constant and characteristic in certain plants—for example, the very minute angular starch-granules of rice are quite different from those of the other cereal grains, which, again, are easily distinguished from those of the potato, shewn in the above figure (*c*); while those of leguminous plants have a somewhat common character (*d*). The peculiarities of starch-granules have been successfully employed in detecting adulterations of food and drugs, and for other purposes of practical utility.



b, Papyrus: pith-like tissue, composed of cells arranged in form of a net-work, so as to leave large intercellular spaces (*ad nat.*).

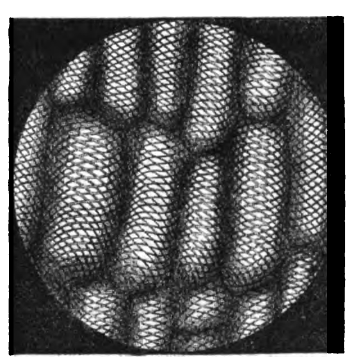


c, Starch-grains of Potato (*ad nat.*).



d, Lentil: cells of seed containing Starch-grains (*ad nat.*).

Instead of holding these cell-contents, and consisting itself of a pellucid membrane, the cell in many cases displays a thickened opaque wall and an empty cavity within. This arises from the deposit of woody matter on the interior surface of the cell-wall, which is seen in the hard stone of the cherry and in the shell of the coco-nut, both of which consist of cellular tissue equally with the softest parts of their respective fruits, and owe their solidity to the indurated woody matter. Instead of having the whole inner surface of the cell covered in this way, the deposited matter may be so arranged as to cover certain parts only: it is often deposited in the form of rings or spiral coils; and in the latter case gives rise to the beautiful spiral cells seen in the roots of epiphytal orchids and in the leaves of bog-mosses—the former are represented in the above drawing (*e*).



e, Spiral tissue from the root of an Epiphytal Orchid (*ad nat.*).

With respect to their general form, cells are exceedingly variable, and are usually greatly modified according to the position in the plant which they occupy. They very commonly present the hexagonal appearance represented in the wood-cut (*a*); but in the bark and young stems, as well as in roots and other parts, they

often assume an oblong form (fig. *e*); sometimes resembling the bricks of a wall set on end, and thus indicating the manner in which plant-structure is built up, as it were, by separate cells cemented together.

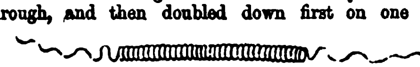
The rounded or spherical form may be regarded as the normal form of the cell, the two modifications to which we have alluded arising from the pressure of spherical or oval cells in contiguity, or special modifications intended to fit them for their place in the structure. In many cases, however, we find cells of a very different form, whose modifications obviously arise from certain special functions which they are designed to perform. The pith-like substance of the rush, used as wick for lamps, consists of cells of a most beautiful stellate form; the free cells or spores of certain algæ are covered with cilia, which give them locomotive power; the cells of hairs are elongated, and often much branched; and the cells of unicellular algæ, such as the Desmideæ and Diatomaceæ, often display the most exquisite symmetry, both in outline and in the elaborate sculpture of their surface. The cotton fibre, which is a cell in peculiar condition, presents the form of a flat twisted band with a thickened margin, a character which is retained by the fibre after it is dressed, spun, and woven into cloth, and even after that cloth has been worn to rags, reduced to pulp, and remanufactured into paper.

In the pulp of leaves and fruit, and in the cellular tissue of the bark, there are frequently cavities found among the cells, which are of several kinds. Those called *receptacles of secretion* are formed for the reception of the oils and other fluids secreted by plants; as, for example, the fragrant oil in the myrtle and the orange, and the turpentine in the pine and fir tribe. Other similar cavities, called *air-cells*, contain oxygen nearly in a pure state, and are called *intercellular spaces*. All these cavities have no distinct membrane to enclose them, but are surrounded by what may be called a wall of cells, which form part of the cellular tissue. The shape and size of these cavities vary exceedingly; the receptacles of secretion, and the air-cells, are often of very great size, and seldom so small as to be invisible to the naked eye: if the stem of the common hippuris or mare's-tail, or the leaf-stalk of a water-lily, be cut across, a beautiful arrangement of these intercellular spaces will be displayed, and the manner in which they are formed by the peculiar arrangement of the plant's cells is shewn in wood-cut *b* (page 69).

Cellular tissue readily decays when the parts composed of it fall from the tree. The carbon it contains is liberated so soon as the vital force by which it was retained has fled, and escapes with the oxygen in the form of carbonic acid gas; whilst the hydrogen, which then forms its principal remaining element, attracts fresh oxygen from the atmosphere, and becoming thus changed into water, rapidly melts away, leaving the inorganic portion to mix with the soil. In leaves, the pulpy parts disappear first, leaving behind the outer cuticle and the nerves or veins, which are of firmer texture; the latter, indeed, being composed principally of woody fibre, the tubes of which have been filled with earthy matter during the process of vegetation, decay very slowly. Those parts of a plant which nature seems to have intended not to be of long duration—such as the fleshy parts of the leaves, the flowers, and the fruit—are composed entirely of cellular tissue of loose texture.

Woody tissue.—It is a familiar fact that the stems of trees and of flowering-plants in general possess a tenacity not found in the leaves and flowers. This is mainly due to the presence of woody tissue, which consists of minute spindle-shaped tubes lying closely together, and overlapping each other at the ends. The strength of these tubes is mainly due to the deposit of woody matter on their inner surface. The value of many plants employed in the arts depends upon the abundance of this tissue: when separated from the softer tissues of the stem and leaves by maceration, it forms the fibre of flax, hemp, China-grass, and other textile substances well known in commerce. In cone-bearing plants, such as the common pine, the woody tissue is very peculiar, each tube exhibiting a series of round discs with a central dot. By carefully studying the peculiarities in such tissues, the sources of unknown timbers may often be determined. In most pines there is a single row of discs on each tube, while in others a double row of opposite discs is observed. In the Araucarias of the southern hemisphere, the discs are angular, and are arranged alternately in several rows; and in the yew and allied plants, the tube has beautiful spiral markings as well as minute discs. Such characters are invaluable to the student of vegetable palæontology.

Vascular tissue has been divided by modern botanists into three kinds—namely, *vascular proper*, *pitted*, and *laticiferous*. Vascular tissue, consists of cylindrical tubes of great delicacy and thinness, called *spiral vessels* and *ducts*. *Spiral vessels* are so called because they contain delicate fibres coiled round in a spiral manner. They are of a light elastic nature, and their fibres, though coiled up naturally like a cork-screw (see fig.), may be unrolled to a considerable extent. If a leaf-stalk of a geranium or strawberry be cut half through, and then doubled down first on one side,



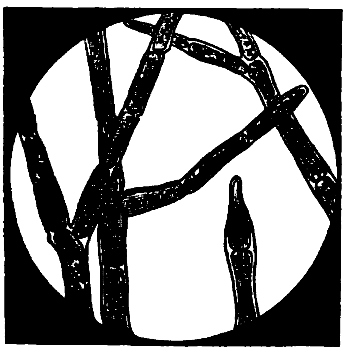
Spiral Vessel.

and then on the other, and the two pieces be then carefully and gently drawn asunder, the transparent membrane will break, and the spirals will unrol so as to appear, when seen with the naked eye, like fine hairs between the two portions of the leaf. Spiral vessels prevail in leaves and flowers, and are found, though more sparingly, in the young greenwood of trees and shrubs; but rarely in the old solid wood and in the roots or in the bark. They are few in coniferous trees; but abundant in palms and their allies. In ferns and the club-mosses they occur occasionally, but are usually replaced by a peculiar kind of vascular tissue, called the *scalariform* tissue, from the ladder-like markings on its angular vessels; the other cryptogamous or flowerless plants are entirely without vascular tissue. These vessels are sometimes called *air-vessels*, because their slender spiral tubes are always found filled with air.

Pitted tissue, sometimes called *dotted ducts*, consists of tubes which, when viewed by transmitted light, appear full of holes, from the numerous dots in the lining of their membrane. The mouths of these tubes are very conspicuous in the wood of the rattan when cut across; they are also to be seen in sections of the oak and the vine; and indeed in most other kinds of wood, as well as in the stems of herbaceous plants. The dotted ducts are larger than the vessels of the other tissues, and are distinctly visible in many kinds of wood, even to the naked eye. Botanists consider them as belonging to cellular tissue, and as consisting only of elongated cells placed end to end, and opening into each other so as to form a kind of tube. Laticiferous tissue consists of tubes which are distinguished from all other kinds of tissue by being branched. They are filled with a mucilaginous fluid called the *latex*, which is always in motion while it remains in the vessels. This milky fluid abounds in the India-rubber and gutta-percha plants, and is seen to exude in abundance from the dandelion when its leaves or stalks are wounded. This fluid, in many plants, contains a large quantity of caoutchouc; it is bland and nutritious in the cow-tree of the Caracas, but in many other plants narcotic and acrid.

Multifarious as are the modifications of the tissues of plants, and the cells and vessels of which they are composed, all have a common origin, all are modifications of the *cell*. The plant begins its existence as a cell, and its whole course of development may be said to be the

evolution of cells. The process of cell-development, or cytogenesis, thus explains the whole phenomena of plant growth and reproduction. To the investigation of this subject, therefore, the attention of vegetable histologists has of late years been specially directed, and the results have appeared in the form of certain theories which have given rise to much angry discussion. It is only needful here to indicate the modes in which cells appear to be usually produced, for no single theory appears to be applicable to all known phenomena. The two principal methods are by free-cell formation and fissiparous, or merismatic, division. By the first, the new cell originates in the protoplasmic fluid contained in a pre-existing one; a nucleus may be present, which forms the centre of vital action, and around which a protoplasmic membrane is formed, which ultimately becomes covered with a coating of cellulose, forming the proper cell-membrane. But a nucleus is not essential to this mode of cell-formation, the protoplasm being the active agent. It will be seen that in this way an old cell becomes developed into two or more (contained) new ones, which increase in size equal to their parent; and in this way the growth of many parts of plants is accomplished. But there is still another mode of cell-development, well seen in a confervoid water-weed (shewn in the adjoining figure) which has of late years choked up Duddingston Loch, near Edinburgh. This consists in cell-division; the inner layer (primordial utricle) of a previously formed cell becomes folded inwards in the middle, so as to divide off the cell into two compartments; a cellulose wall is secreted upon the folded utricle, and thus the division is complete, two cells being formed where only one existed before. In many cases, the development of cells goes on with amazing rapidity. In damp weather, the gigantic puff-ball will grow up in a single night from a mere point to the size of a large gourd, forming on an average not fewer than 20,000 new cells per minute.



Cladophora Fracta, a filamentous fresh-water Alga, in which cell-division is well seen (*ad nat.*).

GENERAL INTEGUMENT AND ITS APPENDAGES.

Submerged plants have the cells of their leaf-tissue directly exposed to the action of the surrounding water; but land-plants usually have all their organs invested in an epidermis or skin, which regulates transpiration, and prevents their tissues becoming dried up. The surface of this epidermis, again, is covered by a very thin structureless layer, called the cuticle. The epidermis is composed of a kind of cellular tissue; but the cells are pressed closely together, and flattened, and they are often filled with air instead of water. The use of the epidermis is to retain a sufficiency of moisture in plants; for should the delicate membrane of which the cells of their tissue are composed become so dry as to lose its elasticity, the different organs would be unable to perform their proper functions. On this account, its thickness is curiously adapted to the conditions under which a plant grows. Plants of very hot countries are supplied with three or even four layers of dense external tissue, in order that the moisture may be retained, notwithstanding the excessive heat and dryness of the climate. But it is necessary that the tissues of plants should not be shut out from the free action of the atmosphere, whence a large proportion of their food is derived. They are therefore provided with peculiar breathing-pores, or stomata, in the epidermis, by which air enters, and from which fluid transpires. Those plants which have numerous pores, or stomata, in their epidermis, require watering oftener than others, and are more easily affected by the heat of the sun. Some curious calculations have been made of the number of these stomata on a given surface, in different plants, the general result of which is that their size, number, and arrangement are strictly in accordance with the requirements of the plant and the function which they perform. In mosses, where the leaves usually consist of a single layer of cells, stomata are confined to the fleshy base of the fruit; but in flowering-plants they chiefly occur on the under surface of the leaf; and this is especially the case in many evergreen shrubs, which are thereby enabled to benefit by the moist exhalations from the soil and herbage beneath, without suffering from a scorching sun. This law is reversed where the habits of the plant require such an adaptation. Water-lilies and other plants whose leaves float on the surface of the water or lie flat on the soil, have no stomata on their under surface, but are supplied with an increased number on their upper surface, which alone is exposed to the action of the atmosphere. The following calculation of the number of stomata in the leaf of the royal water-lily, will serve to indicate the extremely minute size of these bodies and the great numbers of them required by plants: each stomate measures the $\frac{1}{360}$th part of an inch in diameter; one square inch of surface contains 139,843 stomata; so that one ordinary sized leaf of this plant, with a surface of 1850·08 square inches, contains upwards of twenty-five millions of stomata (25,720,937).

In the oleander and in the proteaceous plants of New Holland, the stomata are not equally disposed over the surface, but occur in groups, which are protected by incurved hairs from the excessive action of drought—a remarkable instance of provision for special circumstances of climate.

Hairs are minute prolongations from the epidermis, and are found upon almost every part of plants. Sometimes they cover the whole of the leaf, and at others they are only found on one surface. They are described in general terms as downy, silky, hirsute, bristly, ciliate, &c., according to their aspect and mode of arrangement. The use of hairs is partly to protect the surface of the leaf from the heat of the sun and from drying winds, and partly to collect moisture from the atmosphere. It is known that plants take in nourishment from the atmosphere as well as from the soil; and it is supposed that part of this nourishment is absorbed through the hairs. The hairs of plants are exceedingly variable in size and form, and are either unicellular or multicellular—consisting of one or of many cells. In either case, they may be simple or branched. There are branched unicellular hairs in Cruciferæ, and beautiful stellate hairs in many plants; the latter occur even in the internal cavities—intercellular spaces—of aquatic plants. The sting of the nettle is a beautiful modification of the hair, being a conical tube with a basal bulb, filled with irritant fluid, which shews singular movements under the microscope. The tube is sharp-pointed, and surmounted by a little curved knob; when the plant comes in contact with the hand, or any other body, this knob is knocked off; the sharp point which it protected now penetrates the skin; and the pressure upon the conical sting causes the irritant fluid which it contains to be poured out into the wound. The whole phenomenon is strikingly similar to the mode of action of the animal sting.

Glands.—Although it has been repeatedly stated, in recent works on physiology, that there is no true process of secretion in plants analogous to that of animals, still the latest researches seem to indicate that such a process does exist, and that it is performed by special organs—usually modifications of the epidermis itself or of its

appendages. Thus, in the Cinchonas of South America, we have conical glands, which pour out a gum-resinous matter on their free surface, which is employed by the Peruvians—under name of Oil of Mary—as an external application in various maladies; and the same kind of glands are now found in the bedstraws of our hedgerows. In many monocotyledonous plants large follicular glands of a complex structure have been described, which are probably connected with reproductive phenomena. The honey of many flowers also appears to be a true secretion, poured out upon a free surface of the tissue by special cells, which are not analogous to the fat-cells of animals, to which the so-called vegetable secretions have been likened.

Besides the above-mentioned organs, there are prickles, thorns, and spines. *Prickles* may be called hardened hairs, as they are merely indurated expansions of the epidermis, without any woody fibre; and they may be detached from the branch which bears them without laceration. *Thorns* differ from prickles, in being formed partly of woody fibre; and they cannot be detached from the branch which bears them without lacerating its vessels. They have their origin in buds, and are the result of an arrestment of development, being formed instead of leaves and branches. *Spines* resemble thorns in every respect, except in being found on the leaves and stems of herbaceous plants; while thorns only grow on the trunk and branches of woody plants. When spines grow on leaves, they are always found on the veins which are extensions of the woody fibre.

ORGANS OF NUTRITION.

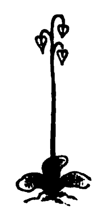
The organs of nutrition are the root, the stem and its branches, and the leaves; and of these organs, the root and the leaves, or some modification of them, exist in every flowering-plant, as the vital functions cannot be carried on without them.

The root (*radix* in Latin) is commonly defined to be that part of a plant which attaches itself to the soil where it grows, or to the substance on which it feeds, and is the principal organ of nutrition. Exceptions to this definition occur, as in the case of some vegetables which grow floating loosely in water, as duck-weed, as well as in the case of others having no root at all. As the nourishment of a plant is derived from the earth, the root is that part which grows in an opposite direction to the stem, and is buried in the ground. It is, in fact, the descending axis. The more common form is the fibrous root as seen in grasses, the fibres being terminated by spongioles, which are the absorbent points. But the main root is often thickened into a tap-root, giving off secondary fibres—globe-shaped, in the turnip—conical, or tapering gradually from the collar to the attenuated fibre, in the carrot—fusiform, or tapering at both ends, in the radish: this latter may be abrupt, where the lower end appears as if cut off, which is exemplified in the devil's bit scabious. In the dahlia, the roots branch off in a fasciculate manner; while in the orchis they are tuberous, being in the form of globe-shaped bodies filled with starchy matter. The so-called tuberous roots of the potato are considered by botanists as merely underground stems, from the circumstance of their having eyes or buds from which branches will spring.

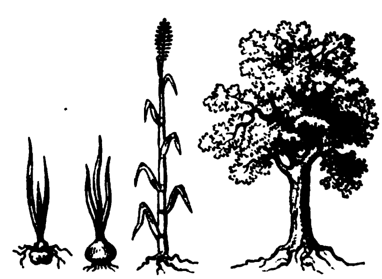
The crown, collar, or life-knot, as it is variously called, is that part which lies between the stem and the root. It is the most essential portion of the whole; for if it be removed, or seriously injured, the plant will inevitably die; whilst the small fibres or rootlets, although an essential part of a plant, may be destroyed at pleasure, so long as the crown remains, for it readily reproduces them. When it is of a slender make, it dries up as the seeds ripen, and the plant soon dies, as the poppy, mignonette, and other annuals.

Roots have a remarkable tendency to grow downwards, or in the direction of the earth's centre; and from experiments, it seems not unlikely that this tendency is to some extent an effect of gravitation. The precise direction, however, is very much influenced by the condition of the soil. Both root and rootlets extend as if in quest of food, and will penetrate sidewise or obliquely to great distances. When plants are by any means prevented from fructifying by seeds, they almost invariably increase by extending their roots or creeping-stems, from distant points of which new plants will spring up. These thus perform the functions of stems; and though the two differ in many respects, yet there are cases where it becomes difficult to distinguish between them. Some species of palms send down aërial roots for the purpose of strengthening their stems, and the same are seen very remarkably in the screw-pines. Many herbaceous plants send out roots in a similar manner when they are earthed up; and trees which grow in unnatural situations, as on a wall or bare rock, send down roots in quest of soil and moisture, which afterwards take the appearance of stems. The willow, maple, gooseberry, and some other plants, may have their roots converted into stems by reversing the plants, and burying the tips of the shoots in the earth, so as to leave the roots in the air. In this case, the branches will soon send out fibrous roots from the joints which have been buried in the earth, and the fibrous part of the old roots withering, the roots themselves will gradually assume the character of branches.

The Stem.—When a plant shews itself above the ground, it evidently manifests a strong tendency to the light. Light, in fact, is essential in bringing it to maturity, and in giving the green colour to its leaves. The stem, with a few exceptions, is always above ground. It is divided from the root by the part called the crown or collar. The space between the collar and the first branch is termed the bole or trunk. The stem of grasses, corn, and reeds, receives the name of culm; the stem of such flowers as the primrose, dodecatheon (see fig.), and the daisy, is undeveloped; hence they are called stemless (acaulescent); the stalk upon which the flowers are borne being termed the scape, or flower-stalk; the running-stem, as in the strawberry and cinquefoil, is termed a runner; a shorter runner that does not root, as in the house-leek, is termed an offset; and a small stem proceeding laterally from a root or stool, a sucker.



The stem, it will be observed, assumes many forms and characters as to bulk, structure, position, place, and



1. 2. 3. 4.

duration. It appears as a corm (*Gladiolus*, 1); a bulb (the onion, 2); a culm (*Arundo*, 3); or as a woody trunk (the oak, 4). When a trunk bears permanent or perennial branches, the plant is termed a tree; when permanent branches arise, not from a distinct trunk, but from near the root, the plant is termed a shrub; and when the whole stem is not woody, and dies down every year, at least as far as the crown of the root, the plant is termed an herb. Trunks which increase by successive layers of new wood on the outside of the old, as the ash and beech, are termed *exogenous;* those which increase by the addition of fibrous matter in the centre, as the

palms, are styled *endogenous;* and those which do not sensibly increase in thickness, and are formed by the adhesion of the leaf-stalks as they spring from the growing point, as the tree-ferns, are said to be *acrogenous.*

Buds, which have various forms, but are generally oval or roundish, consist of the young shoots either of leaf, flower, or twig, and proceed from what is called the axil of a leaf. They are usually formed either early in summer or in autumn, and are so contrived as to preserve from injury the delicate structure within. The outside is composed of tough scales, which are frequently covered with a gummy resin; and they are internally protected by a downy substance interposed between the leaves.

Linnæus applied the term *hybernacula* to leaf-buds, being the 'winter-quarters' of the young branch. With respect to the manner in which the leaves are arranged and folded in the bud, which is termed *vernation,* they may be simply placed in apposition, as in the misletoe; plaited, as in the palm and birch; doubled, as in the rose and oak; embracing, as in the iris and the sage; double embracing, as in valerian, teasel; rolled inwards, as in grasses; rolled outwards, as in rosemary, primrose, &c.; rolled lengthwise, breadthwise, rolled from the tip to the base, or wrapped round the stalk.

Leaves.—Leaves are the grand ornament of plants, and from their number, position, and delicacy of organisation, they are designed to effect an important office in the vegetable economy. Springing from the branches, and exposed in profusion to the atmosphere, they perform the functions of a breathing-apparatus analogous to that of the lungs or gills of animals. A similar purpose at least is designed; for the sap of plants, like the blood of animals, requires to be exposed to the atmospheric influence, in order that it may be suitable for nutrition. This purpose is accomplished by the agency of the leaves, to which the sap, on rising from the roots through the stem and branches, is propelled or attracted, and there both air and light exercise their beneficial influences. Leaves are thus indispensable to the growth of plants, and care should be taken not to injure them; for defoliation, either naturally or by art or accident, instantly arrests the growth, and the failure or diminished expansion of foliage is a certain sign of debility.

A leaf consists generally of two parts—the petiole,

or leaf-stalk; and the lamina, or that part which is broad and thin. Sometimes, however, as in the rose tribe, stipules (*ss*) are attached to the base of the petiole. The leaf-stalk (*a*) is that part which connects the leaf with the branch, and at the base will be found slightly hollowed, in which a bud rests. Sometimes the leaf-stalk is wanting, as in the sow-thistle and catch-fly, and in this case the leaf is said to be sessile, or sitting. The lamina, or broad part of the leaf (*b*), is frequently of a different colour on the under side. This is exemplified in the common silver-weed (*Potentilla anserina*), the leaves of which are hoary on the lower side and green on the upper. Leaves are either *deciduous*—falling in autumn—or *evergreen,* lasting till the following season. Their forms are exceedingly varied—being *simple* or *compound;* and these again are distinguished as oval, lanceolate, hastate, sagittate, pinnate, cordate, &c.

An important character is afforded by the *venation* of leaves—that is, the arrangement of what are called their veins. In exogenous plants—as our timber-trees, for example—the leaf is furnished with a strong midrib, from which secondary veins diverge, at regular distances; and these again branch off into still smaller tertiary veins, whose ramifications form a reticulation over the surface of the leaf. In endogenous plants, on the other hand—as common plantain, corn, and lilies—there is usually no distinct midrib, but several primary veins, which originate in the base of the leaf, and proceed to its apex, being parallel throughout. In many tropical endogens, however, we have a rather more complex form of parallel venation. In these cases, there is a distinct midrib, from which secondary parallel veins diverge on either half of the lamina.

The veins of leaves consist of woody tissue, accompanied by spiral vessels, the interspaces being filled up with the softer parenchyma, or cellular tissue. By maceration, the latter may be made to disappear, so as to leave merely the veins in form of a skeleton-leaf. In aquatic plants, there is a strong tendency to non-development of the parenchyma; thus, in the aquatic ranunculus, the submerged leaves consist merely of veins, while the floating ones are entire; but the most remarkable instance of this occurs in the *Ouvirandra fenestralis,* a plant of recent introduction to Kew Gardens, whose leaves are entirely destitute of parenchyma, being, in fact, beautiful lattice-like skeleton-leaves. The leaves of the royal water-lily are perforated with minute holes at regular intervals; and a view has recently been brought forward to connect this feature of structure with that seen in Ouvirandra, being a beginning, as it were, of a reduction of parenchyma, which is excessive in the latter plant. This is illustrated by the fact, that in the Ouvirandra, an occasional intercostal space *is* filled up with parenchyma, but not entirely, a round opening being left in the centre.

With regard to the manner in which leaves project from the branches, and their distribution over the woody cylinder to which they are attached, every possible variety may be observed. They may be opposite—that is, two leaves growing on either side of the branch, the one directly opposite to the other; alternate, when one leaf springs out on one side of the branch, and another on the opposite side, a little above it, and so on; whorled, or *verticillate,* when a number of leaves grow round the stem from a common knot or joint, as in the bed-straw. The distribution of alternate and opposite, however, is not regular; for in some instances it will be found that the leaves on the lower part of the stem are alternate, whilst those on the upper are opposite.

There are many plants which have few or no leaves, but whose stems are much dilated, presenting a large superficies of parenchymatous exterior to the air and light. It may be remarked that such plants as the common garden rhubarb, which require much moisture, are provided with very broad leaves, which, by their umbrageous character, preserve the soil from being parched.

Green is the most general colour of leaves, but some are red, or purple, or yellow; some appear nearly white, in consequence of being clothed with short woolly or silky hair. Leaves are often variegated in consequence of the non-development of chlorophyll in the cells

of certain parts. They differ much in substance and structure: some are immensely thick and fleshy, as those of the genus aloe; others remarkably thin, as those of the beech. The texture of the surface is also very dissimilar: some are rough, prickly, and wrinkled; others smooth and glossy.

ORGANS OF REPRODUCTION.

The organs of reproduction are the flower, fruit, and seeds; and these, or some modification of them, exist in every perfect *Phanerogamous* or flowering-plant.

Flower.—A flower consists of several distinct parts—the calyx, corolla, stamens, and pistil. A flower is essentially constituted by the presence of the two last, which are the sexual organs. When there is only one of these present, the plant is termed unisexual; but more commonly these organs are both present in the same flower, which is in this case termed hermaphrodite. In some instances, although the same plant bears both male and female organs, it is not hermaphrodite, as these organs occur in different flowers; in others, again, the male and female flowers exist only on different plants. Lastly, male, female, and hermaphrodite flowers are sometimes found mingled together, either on the same or on different plants. Sometimes the male or female organs alone, protected by a small scale, constitute the flower; but in general they are surrounded and protected by the corolla and calyx, which are called the floral envelopes. All these are commonly borne on a stalk called the peduncle (from *pes*, *pedis*, a foot), which, expanding at its extremity, forms the receptacle, or torus, as it has been called, upon which the whole of the parts

aa, anthers; *d*, filament; *b*, stigma, or summit of pistil; *e*, style; *c*, ovary, or seed-vessel; *f*, peduncle; *g*, calyx; *h*, corolla.

above mentioned are supported. What is called the berry in strawberries appears to be nothing more than the receptacle bearing the carpels on its surface.

The *calyx* is the external leafy envelope surrounding the corolla, and in which the latter rests as in a cup. Sometimes it is entire, but more frequently it is divided into segments (*sepals*), which are more or less separated from each other. It is most commonly green, but in some flowers it is highly coloured, and with difficulty to be distinguished from the corolla.

The *corolla* is the conspicuous highly coloured part of the flower or blossom, and consists of several divisions or leafy parts called *petals*, which are articulated at the base, and consequently fall off at the earliest manifestations of maturity or decay. The extensive variety of tints in the flowering part of plants is remarkable. The lower part of the single petal of a corolla is called the claw, corresponding to the stalk of the leaf; and the broad part is called the limb. The corolla is frequently furnished with certain secreting organs, attached to the throat or the base of the petals, called nectaries.

Stamens.—Within the beautiful corolla are observed several small filaments, arranged in a circle around the central parts, and bearing on their summit little oblong bodies; which are usually apparently covered with particles of a fine coloured matter like dust. These are the male parts of reproduction, the stamens, which are always next to the petals—that is, between their base and the base of the seed-organ. It is upon the number and arrangement of the stamens that systematic botanical arrangements of an artificial character have principally been founded. The following are a few characteristics of the number, length, position, direction, &c., of the stamens. The number of stamens in each flower varies from one to twenty, or more. In length they are equal or unequal, and this disproportion is sometimes symmetrical, sometimes not. In position, they may be opposed to the divisions of the petals, or they may alternate with them, which is their normal condition. Sometimes they protrude beyond the corolla, at other times they are wholly included within it. Their direction may be erect, pendent, or horizontal, and their summit is variously inclined to or reflected from the centre of the flower. The filament which supports the anther is most commonly straight and filiform; sometimes, however, it is otherwise. It varies from being as small as a hair, to be large and flat like a petal, and its summit is either pointed or obtuse. On the summit is that essential part the *anther*, which is generally formed of two small membranous sacs, attached immediately to each other, or united by an intermediate connecting body. In form, anthers are subject to great variety, and, like the filaments, they sometimes cohere so as to form a sort of tube.

The pollen contained in the anthers consists of numerous small bodies, which possess in different plants a very different figure, size, and colour. The number of these in a cell, which is very small, sometimes amounts to many thousands. In some flowers, the pollen-grains are transparent; in others, they are of a white, purple, blue, or brown, and more frequently of a yellow colour; and they often display exquisite markings on their surface, which enables the pollen of certain orders to be identified under the microscope. When a grain of pollen is dropped into water, it swells, and sometimes bursts, emitting a minute quantity of granular matter, which is supposed to be the portion more essential to fecundation.

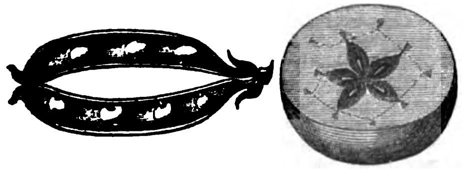
Pistil.—The pistil is the more or less filamentary body which in most plants rises from the centre of the flower terminating the axis of growth, and is surrounded by the stamens. The pistil represents the female part of fructification. Its parts are—1. The *ovary*, containing ovules or rudimentary seeds, and forming its more or less enlarged basal part; 2. The *style*, or filamentous part; and 3. The *stigma*, or enlarged club-shaped or cloven part forming the apex. The first and last of these are essential, and always present; but the intermediate one, the style, is sometimes not developed, as in the poppy, for example. The pistil consists organically of one or more carpels (folded leaves), which may either be syncarpous (united into one) or apocarpous (separate); in the latter case, we have two or more pistils in the flower.

Having thus briefly described the visible reproductive organs, let us now turn to their functional phenomena. When the flower expands, and its essential organs have arrived at maturity, the anther-valves open and emit the pollen-grains; some of these fall upon the stigma, or terminal point of the pistil, where a peculiar tissue, formed of papillary or hair-like cells, is ready to retain them. A curious phenomenon is now observed. The pollen-grain—a single free cell—develops one or more tubes from its surface, these being formed by its inner membrane, which thus grows through the outer one. These tubes are destined to reach the ovules at the base of the pistil, and thus to carry down from the pollen-grain the matter or influence necessary for fertilisation. The tube, accordingly, penetrates the soft tissue of the stigma, and passes down the centre of the pistil, where a loose conducting tissue is specially formed to facilitate its progress. In this way the pollen-tube often acquires

a length several thousand times greater than that of the pollen-cell whence it was produced, its nourishment being derived from the surrounding tissues which envelop it. Mohl regards the development of this filament or tube as indicating a new analogy between the pollen-grain and the spore of cryptogamic plants; for it is, in fact, a process of germination. The length of time required for the growth of the pollen-tube down to the ovule, is very various in different plants, and by no means depends upon the length of the style: thus in the night-flowering cactus, which has a style nine inches long, the pollen-tube reaches the ovules a few hours after the pollen has been applied to the stigma; while in the pine, where there is no proper style, a whole year elapses before the pollen-tubes reach their destination. The lower extremity of the pollen-tube ultimately comes into contact with the ovule, and enters the foramen or micropyle of the latter, so as to reach the embryo sac pre-existing there. According to some physiologists, the apex of the pollen-tube enters or introverts the embryo sac, and develops within itself the rudiment of the future embryo; others think that the tube merely comes into contact with the sac, in which a germinal vesicle has been previously formed ready for impregnation. It is not yet known whether the cavity of the pollen-tube and the embryo sac become actually continuous by absorption of their respective walls at the point of contact; and other questions are still the fertile subjects of learned discussion. However these details may be ultimately settled, it will suffice to state here, in general terms, that the result of the access of the pollen-tube to the ovule, is the production of an embryo in the latter, and that the ovule, with its contained embryo, ultimately ripens into a seed. Fertilisation with pollen is essential for the production of fertile seeds, although the ovule exists previous to the act. Fruits may, in some instances, swell and ripen without any process of fertilisation; but in that case, they will not contain fertile seeds capable of producing new plants.

It is not essential for success in this process that the pollen should fall immediately from the anthers upon the stigma, for we have several historical facts which indicate that pollen may retain its vitality unimpaired, in the manner of seeds. Thus, in the cultivation of the date-tree, it is necessary to bring the fruitful plants under the influence of the male flowers; but on one occasion, during a civil war in Persia, the male date-trees of a whole province were cut down by the invading troops, that the fructification of the fertile trees might be prevented, and the season's crop thus destroyed. But the inhabitants, apprehending such a result, had been careful previously to gather the pollen, which they preserved in closed vessels, and thus were enabled to impregnate their trees when the country was freed from the destroying enemy. The pollen-grains of the date and of the European palm (*Chamærops humilis*) are said to have retained vitality after the lapse of eighteen years.

Seed-vessels are various in form—as, for example, in the case of the pea (*a*), the vessel is a *legume*, or pod; in the apple (*b*), it is a *pome;* and in the filbert, a nut.



a. *b.*

All our esculent fruits are in reality so many vessels or receptacles for the seeds; and the various forms in which they appear are individually suitable to the purposes of their growth. As we have already indicated, the seed contains the *embryo*, or germ, of the future plant, which is generally surrounded by a nutritious substance termed the albumen, destined for the support of the young plant before its organs are sufficiently matured to allow of its supporting itself. This albumen varies very much in quantity, sometimes being much smaller than the embryo; while in other cases, as in the coco-nut, it weighs as many or more ounces than the embryo does grains. Its texture is variable. It is generally fleshy, as in the pea and bean; but sometimes it is farinaceous or floury, as in the wheat and in the marvel of Peru; at other times it is oily, as in linseed; horny, as in the coffee; or even stony, as in the palm-like plant whose seed forms the substance called vegetable ivory. If the embryo consists of one seed-lobe or cotyledon, as the wheat, it is said to be *monocotyledonous;* if of two, as in the beech and oak, *dicotyledonous*—and these terms are generally used respectively for endogenous and exogenous; while cryptogamous, or flowerless plants, from being propagated by spores instead of seeds, are said to be *acotyledonous*—that is, without any cotyledon whatever.

FRUCTIFICATION OF FLOWERLESS PLANTS.

As already stated, the lowest forms in which vegetables make their appearance are those of the *cryptogamous*, or flowerless orders—such as the ferns, lichens, mosses, sea-weeds, and fungi. In these, the mode of fructification is very remarkable, and quite different from that of flowering-plants. They have neither flowers nor seeds, but are propagated by minute unicellular bodies called *spores*.

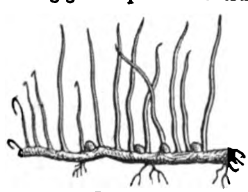
Ferns.—In the ferns (*Filices*), which are the largest and most highly organised of the flowerless orders, little brown spots, called *sori*, may be seen on the under sides of the leaves or fronds (see figs.). Each of these is

Ferns, shewing the Sori on the back of the Fronds.

composed of a number of minute membranous capsules (*thecæ*), which contain the reproductive spores, and which are often furnished with an elastic ring, for assisting in rupturing the spore-case, and thus facilitating the dispersion of the spores. These spores are not the result of a process of fecundation similar to what has been described in the case of flowering-plants; here the order of reproductive phenomena seems to be reversed. Impregnation takes place not upon the mature frond, but upon the infant fern, while as yet scarcely visible to the naked eye. The spores, when scattered over the soil, give rise to minute cellular expansions of tissue resembling liverworts, upon which male and female bodies, called respectively antheridia and archegonia, are produced. The former emit spermatozoids, which move about freely, by means of attached cilia. The archegonia have a central canal, leading down to a large globular cell. According to Count Suminski—to whom we are indebted for a knowledge of these remarkable phenomena—a spermatozoid enters the archegonial canal, reaches the globular cell, and its end is there developed into the embryo cell. This cell divides, and is soon developed into an embryo,

with a bud above and a radicle below; and then the circinate fronds shewing the genuine fern-structure arise. As an order, ferns are very widely distributed, generally consisting of a number of leaf-like members called *fronds*, which are the only visible portion of the plant. In some species, however, the stem rises above ground to the height of thirty or forty feet, forming the well-known *tree-ferns* of New Zealand and Tasmania.

Fern Allies.—In the horse-tails (*Equiseta*) of our marshes and ditches, the spores are placed on bracteated spikes, terminating the stems. Each spore is furnished with an elastic filament, which is at first coiled around it, but which, in its endeavour to uncoil, makes the spore jerk and leap as if alive. The horse-tails are herbaceous perennial plants, having hollow striated stems, these being either simple or branched. In point of size, they are now insignificant members of the vegetable kingdom; but geology has revealed the gigantic proportions they bore in ages long past, when, instead of slender stems of a foot or two high, they reared their gigantic pillar-like trunks to a height of twenty or thirty feet. The spores of the pillworts (*Marsileaceæ*) are enclosed in little ball-like receptacles at the bases of the leaves (see fig.); the club-mosses (*Lycopodiaceæ*) have little cone-like spikes at the tips of their branches, among the scales of which lurk small spores, while large ones occupy the axils of the leaves lower down.



Pillwort.

In the true mosses (*Musci*), the spores are enclosed in urn-shaped capsules, which stand out from the leaves on slender hair-like stalks. In the liverworts and lichens there is a somewhat similar provision; and in the algæ (sea-weeds), the spores are often enclosed in the substance of the plant.

The *fungi*, or mushroom tribe, are extremely diversified in their size, shape, colour, and consistence. They are entirely composed of cellular tissue. The common field-mushroom is one of the best known, and may be cited as typical of the family; but the mould on cheese, stale bread, the mildew on vines, the rust on corn, and many other minute and yet unobserved appearances of a similar nature, are all fungi. Their organs of reproduction consist of spores variously arranged in different tribes, presenting resemblances in some to the lichens, and in others to algæ; but the whole subject of reproduction in fungi requires further investigation, although valuable contributions to our knowledge have recently been made.

There is still much to learn respecting the cryptogamic orders, which yearly receive increasing accessions of students, for it is in these plants that the whole vital phenomena of vegetation can best be studied. 'We are entirely ignorant,' says Professor Lindley, 'of the manner in which the stems of those that are arborescent are developed, and of the course taken by their ascending and descending sap—if indeed in them there really exist currents similar to those of flowering-plants; which may be doubted. We know not in what way the fertilising principle is communicated to the sporules or reproductive grains; the use of the different kinds of reproductive matter found in most tribes is entirely concealed from us. It is even suspected that some of the simplest forms—of algæ and fungi, at least—are the creatures of spontaneous growth: and, in fine, we seem to have discovered little that is positive about the vital functions of those plants, except that they are reproduced by their sporules, which differ from seeds, in germinating from any part of their surface, instead of from two invariable points.'

General Economy of Flowerless Plants.—Insignificant and lowly as the cryptogamia may appear to the eye of the common observer, they are nevertheless important auxiliaries in the operations of nature. It is true that man and his works may suffer from their ravages, that mildew, rust in corn, and other microscopic forms of vegetation, by their rapid increase and destructive effects on the substances from which they spring, may cause incalculable damage; but this very scourge provides an incentive to intelligent prevention and care, while in creation there are no more useful scavengers of decaying matter than the fungi. In a dry season, for example, and on a favourable soil, rust rarely makes its appearance: certain conditions are necessary for its development; and it is to obviating these that the farmer must look for exemption from this destructive malady in his crops. It is said that it arises in many cases from the over-manuring of fields; the grain is overloaded with nourishment, and the dormant fungi, brought into a condition of development, speedily shew their destructive properties. The tendency to rust may be neutralised by steeping the seeds before sowing in a corrosive solution, or strong brine; but the same end may be better secured by not over-manuring, or by a free use of saline manures. Again, most of the fungi existing only by the absorption of fetid exhalations, and rapidly depriving them of their insalubrious properties, execute duties analogous to those of certain tribes of insects—maggot-flies, for instance—and in this respect have been appropriately associated with these animals as the 'scavengers of nature.'

It will now be understood that mould is a fungus, produced by a previous deposit of germs in the tissue or on the surface of the object on which it grows. The proximate cause of its development is generally damp, and without this condition, the embryo remains in a dormant state. Still it may be asked, how cheese happens to have green mould at its very centre?—the reply is, that the germs floating in the atmosphere had various opportunities of finding admission into this article of diet. They may have been deposited on the grass of a field; the grass was eaten by the cow, and the germs were so lodged in the milk; or, what is more probable, the germs fell upon the curd, and there lay concealed till a certain dampness in the cheese brought their vegetative powers into operation. It is well known that the exposure of curd for a day to the atmosphere will have the effect of producing cheese liable to mould. A fully more surprising instance of fungus vegetation in a secluded situation, is that which occurs in the fermenting of yeast and other substances. Fermentation is, in one respect, a chemical process, forming a first step towards dissolution; but the action is also vegetative. The whole mass of matter gradually assumes the condition of active vegetative growth. The fungus germs which had been incorporated in the material begin to live and expand, each being a plant which grows and gives rise to new plants of the same species, until the entire fermenting principle is exhausted.

One great object which nature has in view by the germination and dispersion of the algæ, mosses, and lichens, is clearly that of preparing the way for a higher order of vegetation. It cannot possibly escape our observation that the tendency to vegetate is a power restless and perpetual. We hew a stone from the quarry, and place it in a damp situation, on the ground or in a wall, and shortly a green hue begins to creep over it. This is the commencement of a vegetable growth, produced by germs floated in the atmosphere; and being attached at random to the stone, have been brought to life through the agency of the moisture. Other stones equally exposed, but in dry situations, have also received a clothing of these germs, but circumstances not being suitable, they have not been developed: give the moisture, and they will immediately appear. We hew another stone from the quarry, and build it into the

pier of a bridge, just within the surface of the water: shortly, a kind of green alga will appear; but the wet being in greater abundance, and more continuous, the growth will become more luxuriant than that of the terrestrial wall. Instead of the simple green coating, we have the addition of long filaments resembling hairs (*Conferva*), which float and accommodate themselves to the water around.

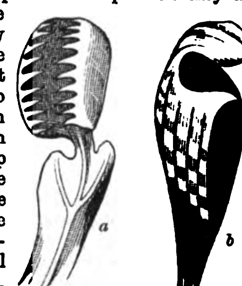
The inquiry may perhaps here be made—supposing that nature designs this species of growth to be a forerunner of a higher order of vegetation, how is that result to be brought about? To answer this, we must take an expansive view of the subject, and not confine ourselves merely to one department of science. Nature is incessantly working out vast ends by humble and scarcely recognisable means. It seems to be a principle that nothing shall remain stationary or unchanged. The whole surface of our planet is every instant altering in its features: mountains are being washed down into the plains, rocks are mouldering into soil, the sea is filling up at one place and encroaching on the land at another, and water-courses are constantly shifting their outlines. The duty of filling up seas, ponds, lakes, and rivers, is consigned to diverse means within the animal and vegetable economy; and one of these is the growth of algæ and other aquatic plants. Take a pond of water, and shut off its means of supply from rivulets and springs, and then observe what an effort nature will make to fill it up. The sides and bottom become speedily covered with a luxuriant crop of confervæ; other plants, which grow only in water, begin to make their appearance, their seeds being wafted thither by winds; at length the superficial matting of herbage is able to support the weight of birds; there is alternate vegetation and decay; finally, the pond is filled up, and a forest of the highest order of trees may in time cover the site of the original humble confervæ. What, indeed, are the extensive peat-mosses but lakes and pools choked with vegetable matter, which remains in a half-reduced condition. Thus we see that the green alga which grows upon stones in the water, humble and apparently insignificant as it is, performs a distinct part in creation necessary to work out the important designs of Providence.

SPECIAL PHENOMENA OF VEGETATION.

In addition to the ordinary functions of the organs, which are common to all plants, there are certain anomalous phenomena which cannot be reduced to regular laws, and which merit notice in this place; the most remarkable of these are the occasional *irritability* and *movements* of plants.

Irritability.—The irritability of animals depends entirely on their nervous system; but as plants have no nervous system, their irritability is more difficult to be accounted for. Dr Darwin indeed asserts that plants are only an inferior kind of animal, and that they, or at least some of them, have a brain and a stomach, and are endowed with the lower senses. According to this fanciful doctrine, the medulla, or pith, was made the seat of sensation, and was considered analogous to the spinal marrow of animals. The doctor, however, had no followers, as his hypothesis presented too many difficulties to be even partially believed. The principal phenomena of vegetable irritability may be divided into three kinds—namely, those caused by atmospheric influence, those depending upon the touch of other bodies, and those which appear to be perfectly spontaneous. Atmospheric influence occasions the closing of the leaves over the extreme point of the young shoot at night, as may be observed in the chickweed and several other common plants. The folding of some flowers in the absence of the sun, and the opening of others as soon as that luminary has withdrawn its beams, are ascribable to a similar cause. The pimpernel closes its flowers on the approach of rain. Most blossoms expand during sunshine; but the evening primrose, on the contrary, will not open its large yellow flowers till the sun has sunk below the horizon; and the night-flowering cereus only expands its magnificent blossoms about midnight. Some flowers are so regular in their hours of opening and shutting, that Linnæus formed what he called *Flora's Time-piece*, in which each hour was represented by the flower which opened or closed at that particular time. Solar light is the principal agent in producing these phenomena; but in some cases flowers have been known to open by artificial light. Decandolle found blossoms expand beneath a lamp nearly as well as beneath the sun itself; and the crocus and gentian, which close at night, have been known to expand as wide as possible when gently exposed to the light and heat of a fire. One of the most remarkable circumstances respecting the effect of atmospheric influences is, that the same causes do not affect all plants, and yet no peculiarity of construction has been discovered in those that are so affected to distinguish them from those that are not.

The irritability produced by external touch is a familiar but little understood phenomenon. The movements of the sensitive plant are well known; and it is also known that if the ripe seed-vessels of the noli-me-tangere be touched in the slightest manner, they will open with elasticity, and scatter their contents. In the same manner the fruit of the squirting cucumber throws out its seeds, and the moist pulp in which they are contained, with great violence, and to a considerable distance. The stamens of the barberry, when touched with a pin, spring forward towards the stigma, after which they return to their original position; while the column of the stylidium, which includes the style and stamens, and which generally hangs on one side, when touched, springs with a jerk to the other side of the flower. The most remarkable instance of irritability by contact is that exhibited by Venus's fly-trap (*Dionæa muscipula*), a native of North America. Its flowers have nothing remarkable about them, except that their petals roll up when they are about to decay; but the leaves are very curiously constructed. They have broad leaf-like petioles, at whose extremity are two rounded fleshy lobes, which form the real leaf, and which are armed with strong sharp spines, three on the blade of each lobe, and a fringe of longer spines round the margin (*a*). When an insect touches the central spines, the leaf collapses, and the poor insect is caught; being either impaled by the central spines, or entrapped by the others. The leaf then remains closed, the fringe of long spines being firmly interlaced and locked together till the body of the insect has decayed. Sarracenia, or side-saddle flower, the leaves of which have a pitcher-shaped petiole (*b*), also forms a trap for flies and other insects, but it does not display irritable phenomena.



a, Leaf of Venus's Fly-trap.
b, Leaf of Sarracenia.

The *spontaneous movements* of plants are equally difficult to be accounted for with those occasioned by atmospheric phenomena or by external touch. It is true that the leaves elongate, the flowers expand, the anthers burst, and the seed-vessels open spontaneously; but these are movements caused by the progressive development of the plant, and subjected to regular laws. The spontaneous movements to which reference is now made are quite different—as, for example, those of the leaves of *Hedysarum gyrans*. This plant has compound leaves, the terminal leaflet of which displays a slight

oscillatory motion; but the side-leaflets have such eccentric movements, as to render it difficult, if not impossible to explain them, and which might appear, indeed, to a fanciful mind as though the whole plant were actuated by a feeling of caprice. Generally, all the leaflets twist and whirl themselves about in an extraordinary manner, though the air of the house in which they grow is perfectly still; but frequently the leaflets on only one side will be affected, and sometimes only a single leaflet will move, or all will become motionless together; and when this is the case, it is quite in vain to attempt to set them again in motion by touching them; though sometimes in a moment, as if from the pure love of mischief, after the touching has ceased, the leaflets will begin to move again as rapidly as before. In like manner, the side-leaflets frequently continue their eccentric movements all night, while the terminal leaflet remains quietly folded up, and apparently fast asleep. Cold stops the motion of the leaves, which begins again so soon as the heat of the stove in which the plant grows is renewed.

Plants may be deprived of their irritability by keeping them without water, when they become flaccid; or by watering them with a poisonous liquid; in which case they lose not only their irritability, but their lives. Life, indeed, appears to be intimately connected with irritability, which exists only in plants in a vigorous and healthy condition. The functions of vitality and irritability may be merely suspended without destroying life, by administering to them the same substances which produce stupor in animals.

Colour.—The colours of plants present many points of interest for the consideration of the student, and are connected with many important phenomena in vegetation. It is to colour, perhaps, more than to form, that vegetation, as a whole, often owes its importance in the landscape. The gay colours of plants usually reside in the corolla, the leaves being usually some shade of green; but in the case of sea-weeds and other cryptogams, the whole plant is often of a bright red, or green, or olive, according to the species, a character which has afforded the basis of the classification of sea-weeds now in use. In flowering-plants, colour is usually of much less importance, and so variable as to give no aid in classification.

The green colour of leaves, and the gay colour of flowers, depend upon different kinds of colouring-matter contained in the cells of the plant, for the cell-walls are without colour themselves. In the green parts of plants, this colouring-matter is in the form of microscopically minute green granules of chlorophyll, which are only produced under the action of light; hence plants grown in the dark are etiolated. The changes which it undergoes, according to its state of oxidation, explain the tints which green leaves acquire in autumn. According to Schleiden, the yellow leaves of autumn contain proportionately more wax than the green leaves of summer, and the yellow rind of ripe fruits more than the green rind of unripe fruits.

The colours of parts not green are due to a different kind of colouring-matter, termed chromule, whose chemical relations to chlorophyll have not been fully investigated. Chromule is usually diffused throughout the sap of the cells; as in the flower of the tulip, for example, a strip of the epidermal tissue of which will shew well, under a common compound microscope, the beautiful arrangement of cells of different colours, so as to give the general effect seen in this gaudily painted flower. In some cases, however, chromule is found in the form of distinct granules. In the intensely blue part of the flower of Strelitzia Reginæ, these are spherical, while in the deep orange parts they consist of slender crescentically twisted filaments floating in coloured cell-sap. Although light is essential to the development of the green colour of leaves, its immediate action is not always required for the development of the chromule of flowers—a fact quite in accordance with the practice of florists, who keep their favourite dahlia and pansy blooms covered up in their later stages. In accordance with this, also, is the fact that flowers grown in the shade are seldom different in colour from those fully exposed to the air and light. The petals of the common buttercup and the lesser celandine are of as brilliant a yellow in town-gardens enveloped in the smoke of London as on any country hill; and roses always maintain their brilliant tints, even when the bushes on which they are produced are evidently dying for want of a clear atmosphere. Flowers may be made to change their colours by the influence of the soil in a most remarkable manner. The petals of the common hydrangea, which are naturally pink, are said to be made blue by planting the shrub in soil impregnated with iron or providing it with charcoal. The change produced in tulips, carnations, heart-eases, &c., is still more extraordinary. The flower of a seedling tulip is generally uniform; and after remaining of this colour two or three seasons, it will suddenly *break*, as the florists term it, into the most brilliant and varied tints of rose, white, yellow, brown, or purple, without leaving any trace of the original colour. To produce this change, florists try a variety of means, all of which have relation to the soil; for example, they sometimes keep their tulips in poor soil, and then suddenly transplant them into one exceedingly rich; or they reverse the process: at other times they change them suddenly from a sandy to a clayey soil. Even the chlorophyll of plants is often developed under circumstances where the influence of light is very slight, and would appear to depend in some measure upon other agents: it is well known that ferns and mosses have been found green in mines where they have grown in almost total darkness; and green and red sea-weeds of the most brilliant tints grow at great depths in the ocean, where the light, being weakened by passing through such an immense body of water, can have but little colouring effect.

Although it has been stated by Ruskin that 'the natural colour of objects never follows form, but is arranged on a different system,' the recent investigations of Professor Dickie on the relations between colour and form in plants seem to indicate a different result. He finds—1. That in polypetalous and gamopetalous flowers, of regular form—such as the primrose, gentian, and pimpernel—the distribution of colour is uniform on the different petals, whether free or in cohesion, whatever be the number of colours present; 2. That flowers whose form is irregular—as, for example, papilionaceous flowers, where certain petals are larger than the others—present an equally irregular distribution of colour, whether one or more colours be present; 3. That different forms of corolla, in the same head of flowers, often present differences of colour; but all of the same form agree also in colour.

The colouring-matter extracted from vegetables is of great economical value, being extensively used in the art of dyeing. Some of these dyes resemble the natural colour of the parts from which they are derived, such as saffron, which is the yellow stigma of a species of crocus; but others, as woad and indigo, are totally dissimilar, being blue or black, when the native vegetable texture is green.

Fragrance.—The cause of fragrance in flowers has never yet been fully explained. We know that all organised bodies consist partly of volatile matters, and thus we can readily account for the odours given out by decaying animal and vegetable substances, as they evidently proceed from the volatile parts being liberated by decomposition. The fragrance of flowers, however, escapes while the plants are in a living state, and that most abundantly when they are in vigorous and healthy condition. Besides the flowers, other parts of living plants frequently exhale fragrant odours—such as the leaves of the myrtle and geranium, and the wood and bark of pines. All these odours proceed from oily or

resinous matters contained in the receptacles of secretion; but the laws which regulate their liberation, and define their physiological uses, are as yet imperfectly known. Some botanists consider them to be part of the excrementitious matter which is thrown off by plants when it is no longer necessary to their growth. It is well known that plants are most fragrant in damp weather. The petals of roses and other flowers retain their fragrance when dried. The fragrance in leaves, bark, and wood, in many cases serves to preserve them from the attacks of insects; as we find that the smell of the red and Bermuda cedars, of which pencils are made, and of camphor—also a vegetable product—are sufficient to keep the moth and some moulds from attacking substances with which they are in contact. The odours of plants are of three kinds: permanent, fugitive, and intermittent. Permanent odours are those given out slowly by the plant, not only whilst it is living, but also after the fragrant part has been separated from the living plant. Of this kind are the odours of fragrant wood, of the dried petals of roses, and some other flowers. Intermittent odours are the most difficult to be accounted for by the vegetable physiologist. It is well known that the night-smelling stock, and several other plants, which are entirely devoid of scent during the day, are delightfully fragrant during the night. One of the orchideous plants produces its powerful aromatic scent only when exposed to the direct rays of the sun; and the flower of the night-blowing cereus is said to be fragrant only at intervals of about half-an-hour during the time of its expansion, preserving the same kind of intermittence even when separated from the stem.

Tastes.—The tastes produced by vegetable substances are generally recognised as sweet, acid, bitter, astringent, austere, or acrid. The juice of the sugar-cane, for example, is sweet; that of an unripe apple, acid; the aloe, bitter; the leaf of the bramble, astringent; and the cranberry, austere. It has been already stated that the ascending sap is at first insipid, and that it gradually acquires the peculiar taste of the plant; but it is only in the descending juice that the taste-yielding principle is fully developed. Why the taste of one vegetable should differ from that of another grown in the same soil, the physiologist is unable to determine; he as yet only understands a few of the causes by which tastes may be modified or destroyed. The principal influences which modify the tastes of plants are atmospheric and solar; light, exposure, and warmth being those under which taste, as well as all other qualities of vegetables, are most fully developed. Every one is acquainted with the blanching effects of *earthing*, as exhibited in celery or in the shoots of the common rhubarb. The fruits grown in our own island during a wet and sunless season, are insipid compared with what they are in a dry and bright summer; and the general vegetation of the arctic and temperate regions is less powerful in kind than that of the tropics. As a general law, it may be stated that the drier and warmer the situation, the more exposed to light, and the slower the growth of any vegetable, the more intense is its peculiar flavour.

Luminosity, Heat, Electricity.—The luminosity of plants—that is, the evolution of light either from living or dead vegetable structure—is a rare and curious phenomenon. Flowers of an orange colour, as the marigold and nasturtium, have been occasionally observed to present a luminous appearance on still warm evenings; this light being either in the form of slight electric-like sparks, or steadier, like the phosphorescence of the glow-worm. Certain fungi, which grow in warm and moist situations, produce a similar phosphorescence; and decaying vegetables, like dead animal matter, have been observed to emit the same kind of luminosity. This phenomenon seems connected with the absorption of oxygen; and the parts emitting it are said to be most luminous when immersed in pure oxygen, and cease to emit it when excluded from that element.

The evolution of heat by living plants is a more common phenomenon. We are aware that warm-blooded animals have the power of keeping up a certain temperature within them, which varies at certain stages of their growth, and perhaps periodically. This result is obtained by respiration—the oxygen of the atmosphere uniting with the carbon of their blood, and producing a kind of combustion. A similar, though less understood phenomenon, seems to take place in the respiration of plants. In germination, heat is sensibly evolved; a piece of ice placed on a growing leaf-bud will dissolve, when it would remain unchanged in the open air; and experiment has proved that the surface of plants is three or four degrees higher than the surrounding medium. Again, the internal temperature of a large trunk is always higher than the surrounding atmosphere, and though young shoots are sometimes frozen through, the general structure both of the wood and bark is such as to conduct heat so slowly, that the internal warmth is seldom reduced beyond what seems necessary to the maintenance of vitality. Generally speaking, it may be asserted that plants possess an internal vital temperature, and that in the so-called process of respiration—the giving off of carbonic acid or oxygen, as the case may be—a certain degree of heat is evolved; but precise experimental results are wanting. During the flowering of certain plants, such as species of Arum and the Victoria Regia, a sensible amount of heat is evolved, raising the temperature inside the flower higher than that of the surrounding atmosphere.

The connection of electricity with vegetable growth has recently excited the attention of physiologists; but little positive information has yet been ascertained. It has been long known that growth takes place with great rapidity during thundery weather; but this may result from the nitrogenised products of the showers which then fall, as well as from the effects of electricity. The progressive states of vegetable growth are the result of chemical changes; and as these changes are more or less accompanied by electricity, it is supposed that plants evolve electricity as well as heat. The general electric state of plants is said to be *negative;* and some have attempted to connect the luxuriant vegetation of the tropics with the thunder-storms of these regions, on the supposition that when the atmosphere is *positively* electrified, the two opposite states will give rise to such commotions. Of late years, attempts have been made to apply the principle to agriculture; conducting-wires have been laid around experimental plots, but with such varied, and even contradictory results, as to preclude anything like a determinate conclusion.

SECRETIONS AND EXCRETIONS OF PLANTS.

Substances of varied properties are secreted by plants, and otherwise formed in their tissues according to their respective natures, and their healthy or diseased condition at the time of secretion. Some of these substances are produced by the ascending sap; but the greater number are deposited by the elaborated or proper juice, and consequently are seldom secreted during spring or early summer. The intensity of those derived from the latter source depends in a great measure upon the influence of solar light; hence they are much stronger, and more abundantly produced, in tropical than in temperate climates. From the manner in which many of these are deposited or ejected, they appear to be of no utility in the vegetable economy. Some of them may be regarded as *excretions* as well as *secretions;* but whether they are to be considered as essential components of the sap, or evacuations necessary to the healthy condition of the organs, has not yet been determined. Being exceedingly varied in their properties, they are of great utility to man as articles of food, medicine, ornament, and luxury.

The economical applications of vegetable secretions and excretions are so numerous, that it would be impossible, in our limited space, to enter upon anything like details. It is even difficult to attempt any classification of them; for, though differing in their properties and external appearance, many of them are identical in chemical composition, and, subjected to peculiar treatment, readily pass into new and singular combinations. Some, for instance, are saccharine, as the juice of the sugar-cane. Many are oleaginous, balsamic, or resinous; some are narcotic, aromatic, or mucilaginous; while others are astringent, purgative, or poisonous. For examples of these divisions, the reader has only to recall to mind such substances as palm and olive oil, myrrh, resin, opium, camphor, gum-arabic, tannin, gamboge, prussic acid, aloes, colocynth, and a thousand others of everyday familiarity.

Besides the proper excretions and secretions, there are several adventitious substances found in plants, which are not the products of vital organisation. Lime, for instance, is found in the ashes of many plants in union with acids; sometimes it is excreted in the form of a thin crust on their leaves, and in other cases in peculiar cells. Silica also occurs in considerable quantities, especially in the stems of reeds and grasses; it forms the glossy pellicle of the cane, and is sometimes found in the joints of the bamboo, where it is deposited in a soft pasty mass, called *tabasheer*, which ultimately hardens into pure semi-transparent silica. Besides these earths, there are various metallic oxides and salts, and the well-known alkalies—potash and soda. The physiological uses of such products are but imperfectly known. Many of them—such as starch, gum, sugar, and the fixed oils—directly administer to the support of the young plant and to the formation of new tissues. Others, again—such as silica and metallic oxides—give hardness and stability to the stems and branches; some give elasticity and pliancy to the young shoots, thereby preventing them from being broken by winds; and several—as tannin, for example—seem to administer to the durability of the woody fibre by their properties of resisting putrefaction.

METAMORPHOSES OF PLANTS.

The metamorphoses of plants, in the general sense of the term, form one of the most interesting sections of Vegetable Physiology. Technically, it is termed *Morphology*—that is, a consideration of the changes and transformations which various parts of plants undergo, either from natural or artificial causes. We know, for instance, that many plants are made to change their appearance and qualities by cultivation; that by grafting, hybridising, and other means, the gardener can change the size, colour, and qualities of his fruits and flowers: and that analogous changes take place in a state of nature—such as the conversion of petals into leaves, and leaves and branches into thorns and spines. It is also well known that flowers become double by changing their stamens into petals; and it is from a knowledge of such facts that botanists have asserted that all the parts of the flower and fruit, as well as the appendages of the stem or ascending axis, are modifications of a single typical organ, and may be considered *as leaves adapted to special purposes*. This doctrine, at first broached by Linnæus, and subsequently expounded by the German poet Goethe, is now very generally adopted.

The law which it seeks to establish may be stated to be this: that all the appendages of a plant have a common origin with the leaf, and may therefore successively assume the form and appearance of that primary organ. The branches of the stem take their origin from leaf-buds, and are clothed with branches and leaves by the same process as in the main stem. Towards the point of fructification, the leaves assume the form of bracts; these, again, are succeeded by the leaf-like sepals of the calyx; and next by the petals of the corolla. Within the petals are the stamens—which sometimes assume a leafy form—next the pistil, and ultimately the seed-vessels. Even the seeds are but leaves in another form. Thus, the growth and reproduction of plants may be regarded as a circle of leaf-like changes, the leaf, or some modification of it, being in all cases the organ which administers to the functions of vitality. We need scarcely enumerate instances of these conversions, for every one who has intelligently observed the common garden-plants around him, must have sometimes felt the difficulty of distinguishing between calyx and corolla—must have seen stamens assume the aspect of petals, and not unfrequently the whole floral organs appear green and leafy. And just as there is an indubitable passage from leaves to every other organ, so may any one organ be found to revert to the primary form of the leaf. One of the most striking examples to which attention can be drawn is that of the cherry. To say that the fleshy fruit of the cherry, with its central stone, is merely a modified leaf, may seem paradoxical; but such is the fact, as any one may demonstrate by examining the blossom of the double-flowered cherry, so common in shrubberies: in this variety, the stamens are changed into petals, and the ovary into a green leaf!

By cultivation and other artificial treatment, certain peculiarities assume in some plants a wonderful degree of permanency, and may be transmitted to successive races; though, generally speaking, if the artificial stimulus be not kept up, plants will return to their normal or natural condition. There are no such roots or tubers in nature as our cultivated beet, carrot, and parsnip; no leaf-buds like the thick succulent *hearting* of the cabbage; no flowers like our double roses, carnations, and ranunculuses; and no fruits like our delicious pears and apples.

The *hybridism* of plants is closely allied to the subject of morphology, and is, in fact, a process of transformation of an artificial character. As among animals two distinct species of the same genus will produce an intermediate offspring—such as the *mule*, which is the offspring of the horse and ass—so among vegetables, two species belonging to the same genus can be made to produce a *hybrid;* that is, a new plant possessed of characters intermediate between its parents. This power of hybridising is more prevalent among vegetables than animals; for the different species of *many* genera of plants are capable of producing this effect, if the pollen of one species be put upon the stigma of another. And this crossing may even be applied to separate genera. Hybrids have not the power of perpetuating their kind like naturally distinct species; for, though occasionally fertile in the second and third generations, they have never been known to continue so permanently. But though incapable of propagating beyond a limited period, the pollen of the parent species may be made to fertilise them, or their pollen to fertilise the parent; but in either case the new offspring gradually merges into the original species. Thus nature has wisely set a limit to the intermingling of species, by which they are preserved from ultimately running into confusion and disorder.

In an economical point of view, hybridism is of great value to man. By a knowledge of its principles, he has been enabled to modify the characters of natural species, so as to adapt them to his special purposes; and thus have arisen most of those beautiful varieties of what are termed florists' flowers, which now adorn the flower-garden. So also by crossing varieties of the same species, our grains, fruits, and kitchen vegetables have been brought to a high state of perfection. The size of one species has been assiduously amalgamated with the durability of another; the beauty of a third with the flavour or odour of a fourth; and so on with other qualities. The principles of hybridism will yet be more extensively applied; and it is not too much to expect that the perfection of our field and forest produce will yet rival that of our orchards and gardens.

SYSTEMATIC BOTANY.

BOTANY is the science whose purpose it is to investigate the Vegetable Kingdom. *Vegetable Physiology*—treated in the preceding sheet—is that department of the subject which explains the organisation and vital functions of plants; *Systematic Botany*, that which recognises their arrangement into groups, according to their form and structure. The former relates to functions which are common to all vegetables; the latter takes notice only of such peculiarities as serve to distinguish one species from another, or one family from another family. The vegetable kingdom is supposed to contain upwards of 100,000 species; and therefore, without some system of arrangement into smaller groups and orders, it would be difficult to acquire a knowledge of the special characteristics of plants, or to convey that knowledge to others by any process of description. It is the aim of Systematic Botany to obviate this difficulty, by classifying plants according to certain types and resemblances which are common to a number of species; thus making one description equally applicable to a class as to a species.

The advantages of classification in lessening the labour of memory and description, become strikingly apparent when we reflect on the difficulty which would exist were each plant to be known by an entirely distinct name. For example, there are many species of roses, all of which are known by the generic term *Rosa*, each having a second or specific name to designate it separately, as *R. centifolia*, *R. damascena*, &c. Now, if a botanist hear of a plant called *Rosa*, though its specific name be quite new to him, he has instantly a general idea of what sort of plant it is, from his previous knowledge of the common characteristics which belong to the genus *Rosa*. The principle of classification is to assemble those plants which bear most resemblance to each other; and this has been done in different ways by different botanists; each method being called the *system* of the individual who devised it—as Tournefort's system, Linnæus's system, Jussieu's system. Of the several systems which have been suggested, only two are in use at the present time—namely, that of Linnæus, the great Swedish naturalist (1707–1778); and the Natural System, in its numerous modifications, that of Jussieu, an eminent French botanist, who, during the long period between 1789 and 1836, was closely engaged in improving the nomenclature and arrangement of the vegetable kingdom, having afforded the basis of those mostly in use.

The system of Linnæus is founded on the *sexes* in plants—the number, situation, proportion, and connection of stamens and pistils, which are regarded as respectively the male and female organs, being chosen to supply characters for the classes and orders. This system appears at first sight extremely simple, as it depends entirely on the counting of so many visible parts; but it is very uncertain, as the number of stamens often differ, from accidental circumstances, in plants of the same genus; and it tells nothing of the plant but its class and order, which lead only to the discovery of its technical name, as plants of the most opposite qualities frequently agree in the number and disposal of their sexual organs. This mode of classification is known among botanists as the Sexual System, or the *Artificial System*, because it is founded on mere artificial enumeration, on a single series of characters, and not upon natural qualities or resemblances of the plants so arranged. That of Jussieu, on the contrary, is founded on the natural affinities of vegetables; and the botanist who is acquainted with its principles can at first sight assign any plant to its proper class and order, as there is always a general resemblance among the plants belonging to the same natural order. Again, knowing the order, which is usually typified by some common plant, he can predict as to its properties—a species of information which the artificial system does not attempt to convey. Jussieu's method has been greatly improved since the time it was suggested, particularly by the late Professor De Candolle of Geneva; and it is his modification of the original plan, with further improvements, which constitutes the most generally adopted *Natural System* of the present day.

According to both systems, plants are divided into classes, orders, genera, species, and varieties. A *class* consists of plants resembling each other in some grand leading feature, and as strongly differing from another class as mammalia do from birds, for example. Thus, flowering-plants with one cotyledon, whose trunks increase in thickness from within—as the palm—form a distinct class; while flowering-plants with two cotyledons, and whose trunks increase by external layers, constitute another class. An *order* consists of plants still more closely allied, so that many orders may be found in the same class. Thus, as ruminant or cud-chewing animals form an order of mammalia, so do the leguminous or pod-bearing plants constitute an order of dicotyledonous vegetation. A *genus* consists of plants so very closely allied, that they may be compared to members of the same family. The pea, for example, constitutes a genus of leguminous plants, just as sheep form a family of the ruminants. A *species* may be compared to one of the members which compose the family; thus the garden-pea and sea-pea are different species of the same genus. A *variety* is merely a departure from the common appearance of the species in trivial characters, or differences which arise from climate, situation, greater or less humidity of soil, and other accidental causes. The boundaries between species and varieties are often very vague, Mr Babington and other botanists regarding those plants as species which others consider mere varieties; but much doubt might be removed by attending to the fact, that a species reproduces itself from seed, and is always persistent under the same circumstances, whereas a variety has often a tendency to revert to its parent species, unless propagated by cuttings, and fostered by artificial means. A *hybrid* is a plant raised by fecundating the stigma of one species with the pollen of another—a process which occasionally occurs among plants in a wild state, but is more common in cultivation. Unless perpetuated by artificial processes, they soon die out, or revert to their original stock.

In botanical nomenclature, the name of every plant consists of two words; the first is the name of the genus, and the second that of the species—as, for example, *Quercus alba*, the white oak. When three names are given, the third signifies that the plant is a variety; and this is sometimes more strongly marked by using the contraction *var.* before the third name—as, *Quercus Ilex* var. *crispa*, the curled-leaved variety of that tree. The third name is for the most part omitted in botanical catalogues, and the varieties indicated by letters of the Greek alphabet—observing that the varieties begin with the letter β—as, *Quercus Ilex β. crispa*.

The primary arrangement of plants, according both to the artificial and natural system, is into those with flowers and those without flowers. The first division, or that which includes the flowering-plants, is distinguished

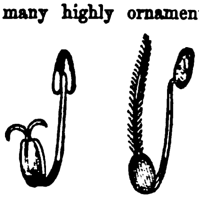
by the name PHANEROGAMIA, and in them the organs of reproduction are apparent. It comprehends all the trees and shrubs used in the economical arts, as well as the common ornamental plants of our gardens, and, in short, all those that have distinct organs—as leaves, branches, flowers, and proper seeds. The second division, known by the term CRYPTOGAMIA, embraces, as the name implies, those plants in which the organs of reproduction are not apparent—as the ferns, lichens, mosses, and sea-weeds. They have no flowers nor seeds, in the common acceptation of these words, and their *fronds* or leaves are very different from those of flowering-plants; instead of flowers, fruit, and seed, they are furnished with little cases or *thecæ*, and in these are lodged the reproductive spores, minute as the particles of the finest dust. Here the resemblance between the two systems ceases—their classes and orders being arranged on totally different principles. We shall present, in the first place, an outline of the Linnæan system, both on account of its priority and simplicity, and as an initiatory step to gaining a knowledge of the different forms of flowers. It is true that it is now disused by most men of science; but for the reasons already stated, as well as from the fact that many excellent works have been arranged on its plan, it is necessary that the general reader, as well as the botanist, should have an acquaintance with its leading features.

THE LINNÆAN SYSTEM.

The sexuality of plants had been discovered before the time of Linnæus; but as far as is now known, he was the first who suggested the adoption of this characteristic as a basis of classification. According to his system, the vegetable kingdom is divided into twenty-four *Classes*, founded upon the number, the proportionate lengths, the connection, or the situation of the stamens. These classes are again subdivided each into one or more *Orders*, depending upon the number of the pistils, the presence or apparent absence of a seed-vessel, its shape, or the number and connection of the stamens, or on the arrangement of the florets. Terms compounded of the Greek numerals and the word *andria*, or male, are for the most part used to designate the classes; and similar compounds of these numerals, and the word *gynia*, or female, are employed to designate most of the orders. The following synopsis presents at one view an outline of the system:—

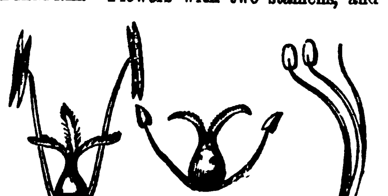
CLASSES.		ORDERS.
1. Monandria, . . .	1 stamen, ...	has 2—Monogynia and Digynia, or 1 and 2 pistils.
2. Diandria, ...	2 stamens, ...	″ 3—Monogynia, Digynia, and Trigynia.
3. Triandria, ...	3 ″ , ...	″ 3—Monogynia, Digynia, and Trigynia.
4. Tetrandria, . . .	4 ″ , ...	″ 3—Monogynia, Digynia, and Tetragynia.
5. Pentandria, ...	5 ″ , ...	″ 6—Mono., Di., Tri., Tetra., Pentagynia, and Polygynia.
6. Hexandria, . . .	6 ″ , ...	″ 4—Monogynia, Digynia, Trigynia, and Polygynia.
7. Heptandria, ...	7 ″ , ...	″ 4—Monogynia, Digynia, Tetragynia, and Heptagynia.
8. Octandria, . . .	8 ″ , ...	″ 4—Monogynia, Digynia, Trigynia, and Tetragynia.
9. Enneandria, ...	9 ″ , ...	″ 3—Monogynia, Trigynia, and Hexagynia.
10. Decandria, ...	10 ″ , ...	″ 5—Monogynia, Digynia. Trigynia, Pentag., and Decagynia.
11. Dodecandria, from 12 to 19	″ , ...	″ 7—Mono., Di., Tri., Tetra., Penta., Hexa., and Dodecagynia.
12. Icosandria, ″ 20 or more	″ , on the corolla or calyx,	″ 3—Monogynia, Di.-Pentagynia, and Polygynia.
13. Polyandria, ″ 20 or more	″ , on the receptacle, .	″ 6—Mono., Di., Tri., Tetra., Pentagynia, and Polygynia.
14. Didynamia, ...	4 ″ , 2 long and 2 short, .	″ 2—Gymnospermæ and Angiospermæ.
15. Tetradynamia, . . .	6 ″ , 4 long and 2 short,	″ 2—Siliculosa and Siliquosa.
16. Monadelphia, all the filaments united, ...		″ 8—Tri., Pent., Hex., Hept., Oct., Dec., Dodec., and Polyand.
17. Diadelphia, filaments united into two sets, ...		″ 4—Pentandria, Hexandria, Octandria, and Decandria.
18. Polyadelphia, filaments in three or more sets, ...		″ 2—Decandria and Polyandria.
19. Syngenesia, five stamens united by their anthers, . . .		″ 5—Polyg.-Æqualis, Superfl., Necess., Frustranea, Segregata.
20. Gynandria, the stamens growing on the pistil, ...		″ 3—Monandria, Diandria, and Hexandria.
21. Monœcia, flowers with stam., others with pist. on same plant,		″ 10—Mona., Di., Tri., Tet., Pen., Hex., Oct., Icos., Polyan., Monadelphia.
22. Diœcia, stamens on one plant, and pistils on another, .		″ 13—Mo., Di., Tr., Tet., Pen., Hex., Oc., En., Dec., Do., Ic., Polyand., and Monadelphia.
23. Polygamia, unisex. or bisex. flowers on same or diff. plants,		″ 2—Monœcia, Diœcia.
24. Cryptogamia—inconspicuous flowers, ...		″ 5—Filices, Musci, Lichenes, Fungi, Algæ.

I. MONANDRIA.—The first order of this class contains many highly ornamental exotics, chiefly reed-looking herbaceous plants, with large leaves and showy flowers. The seeds and roots of many of these are used in medicine as well as by the dyer—as tumeric, arrow-root, and *Zingiber officinale*, the common ginger of commerce. Their predominating qualities are aromatic. Several of the genera are British—as hippuris, glass-wort, &c. The second order, DIGYNIA, contains *Callitriche*, the water-starwort, frequently met with in our ditches. There is another plant, sometimes sown in borders as an ornamental annual, which also belongs to it—namely, *Blitum capitatum*, the strawberry blite.



Digynia. Monogynia.

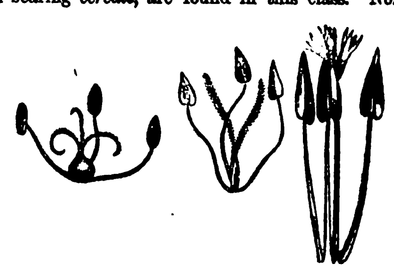
II. DIANDRIA.—Flowers with two stamens, and with



Trigynia. Digynia. Monogynia.

one, two, or three pistils; thus constituting three orders, of which there are upwards of sixty genera. The first order, MONOGYNIA, contains by far the greater number of the genera. Here we find the useful olive, the fragrant jasmine, the lilac, and many evergreen shrubs. Nor are the herbaceous members of the order less prized: the wild and cultivated speedwells, and the elegant slipper-wort, are among the choicest gifts of Flora. The rosemary, and the numerous species of sage, are ranked in this order, though some botanists have suggested the removal of the latter plant to the class DIDYNAMIA, because, in addition to the two perfect stamens, there are the rudiments of two others in the flower.

III. TRIANDRIA.—Almost all the grasses, including the grain-bearing *cereals*, are found in this class. Nor are

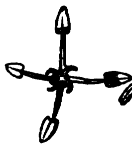


Trigynia. Digynia. Monogynia.

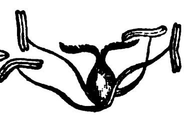
the other genera less remarkable for the beauty of their flowers, than are the grasses and cereals for their

usefulness. The well-known crocus, the corn-flag, and iris, and many allied foreign genera, are among the chief ornaments of our gardens, thus compensating in some measure for their want of usefulness when compared with their associates the cereals.

IV. Tetrandria.—Flowers with four stamens *of equal length*. The equal length of the stamen should be specially kept in mind, because the fourteenth class (Didynamia) has also four stamens, but of these two are longer than the others. Many of the genera of this class are beautiful shrubs and trees, chiefly natives of the Cape of Good Hope and New Holland—as the *Proteas*, *Hakias*, *Banksias*, and the splendid waratah or *Telopia speciosissima*. Several fine ornamental exotics—as the *Ixoras*, for instance—belong to this class, as well as many hardy plants, both shrubs and herbs, natives of Europe, such as *Buffonia tenuifolia*—named after the



Tetragynia.

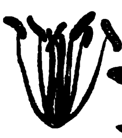


Digynia.

Monogynia.

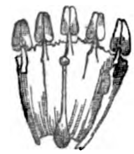
celebrated naturalist Count de Buffon—the witch-hazel, a hardy North American tree; the well-known holly, which as a hedge-plant and ornamental evergreen is unrivalled, and whose timber, when it has attained full size, is solid, white, and of remarkably fine grain, and much used by musical instrument-makers and other artists. The common pond-weeds (*Potamogeton*), so frequent in our slow-running rivers, also belong to this class.

V. Pentandria.—Here we find the *Asclepias*, with its curiously constructed flowers, and the no less remarkable *Stapelia*, a family of plants, bearing flowers of uncommon character both in shape and colour, and moreover



Trigynia.

Digynia.



Monogynia.

diffusing a scent so loathsome, that blow-flies lay their eggs on the petals! Here also we find the remarkable English parasitical plant, the dodder (*Cuscuta Europæa*), and the stately elm-tree, so useful both for ornament and timber; the ornamental laurustine, the elder, and other well-known plants. The sumach family, so variously useful in the arts, is also ranked here; the beautiful Grass of Parnassus, so common in our marshes; the pansy, the primrose, forget-me-not, and other plants; but we can only add the names of one or two more, such as the highly ornamental family of *Crassula*, a tribe of succulents chiefly from the Cape of Good Hope; the superlatively useful flax; the neat thrift, used for the edgings of walks in gardens; the *Myosurus minimus*, or mouse-tail, &c.

Pentagynia.

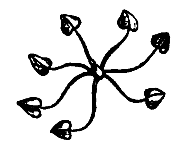
Tetragynia.

VI. Hexandria.—Flowers with six stamens of *equal length*. By far the greater number of our bulbous flowering and culinary plants—as the narcissus, the lilies, the long-lived American aloe, the magnificent Crinum and Pancratium, the unequalled fruit of the pine-apple, and the equally useful onion, asparagus, &c.—belong to this class. The plants are chiefly herbaceous, and are found in every clime from the torrid to the arctic zone, in the burning sands of Africa, and amid the snows of Siberia. One of them (rice) is most important to the inhabitants of tropical countries, and to those of the warmer parts of the temperate zones. It is the staff of life in India, and is cultivated on every spot of level ground where there is a command of water for irrigation. Here also we have the elegant Trillium, the meadow saffron, and the water-plantain.

Digynia.

VII. Heptandria.—This class is illustrated by the *Æsculus* and *Pavia*, better known by the name horse-chestnuts. They are among the most ornamental of our forest-trees, though they are not natives. The flowers of the common sort are well known; one or two of the pavias have bright red flowers, and are most striking objects in ornamental scenery. The common horse-chestnut yields great crops of nuts, which are used for the food of some domestic animals. It is remarkable that among above 3000 genera, only one should occur with seven stamens and seven styles; indeed, as Rousseau remarks, nature has neglected the number seven in her arrangement of vegetable structures.

Digynia.



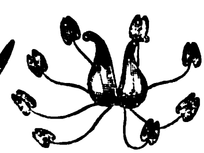
Monogynia.

Heptagynia.

Tetragynia.

VIII. Octandria.—The heaths are the most conspicuous and numerous examples of the class. Of this family alone there are 543 species already described, chiefly natives of the southern parts of Africa. A few are found in Britain, and several in other parts of Europe. The curious *Rhexia*, the day and night flowering *Œnothera*, and the elegant *Fuchsia*, are found in this class; so also is the well-known *Mezereon*, and

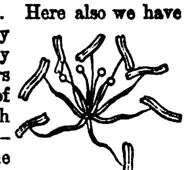
Trigynia.



Digynia.

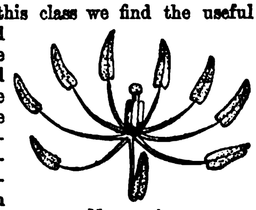
Monogynia.

many exotic genera of great beauty. Here also we have the sea-side grape, and soapberry of the West Indies; the curiously organised *Bryophyllum*, which bears viviparous progeny on the edges of its leaves, in addition to those which are yielded by the perfect seeds—a remarkable departure from the usual way in which plants produce viviparous offspring.



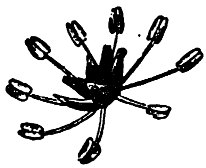
Tetragynia.

IX. Enneandria.—In this class we find the useful and fragrant cinnamon, and the famous laurel, whence so many medicinal oils and other useful substances are extracted; as well as the excellent medical and culinary rhubarb; the flowering rush of Britain (*Butomus umbellatus*), which is common in ponds and ditches in a few localities in this country, and is one of

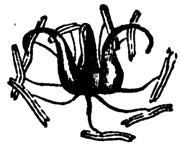


Monogynia.

our most showy wild plants. The leaves are partly under and partly above water. The flower-stalk is



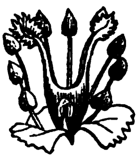
Hexagynia.



Trigynia.

elevated a few feet in the air, and bears an umbel or tuft of very beautiful flowers, which are pale and tinged with pink or blush colour, or frequently entirely purple.

X. Decandria.—Many of the species of this class are brilliantly flowering shrubs; we have the *Kalmias*, *Ledums*, *Rhododendrons*, *Andromedas*, &c., plants as generally admired as they are universally cultivated: we have also the arbutus, the fine aromatic-scented storax-tree, and many other exotics of the greatest beauty; the *Hydrangea*, the extensive genus *Saxifraga*, and the equally extensive family of *Dianthus*, which includes the carnation, pink, sweet-william, and other species and varieties of that favourite tribe. The catchflies, stitchworts, and sandworts, are all found here; as



Digynia.

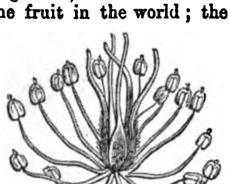
Decagynia.

Pentagynia.

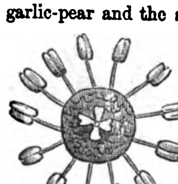
Trigynia.

also the *Cotyledons* and the *Oxalises* of the Cape of Good Hope; the *Sedums* of Europe; the lychnis, mouse-ear, chickweed, the common spurrey, and *Phytolacca*.

XI. Dodecandria.—There is no plant yet discovered with eleven stamens, and all those of this class have the number varying from twelve to nineteen. The class, among many fine tropical plants, includes the celebrated mangosteen, said to be the most delicious and wholesome fruit in the world; the garlic-pear and the showy



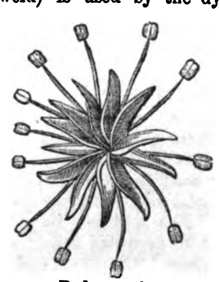
Pentagynia.



Tetragynia.

British plant which ornaments the banks of our rivers in some parts of the country during summer, the *Lythrum Salicaria;* agrimony, common on road-sides; and *Reseda*, one species of which (weld) is used by the dyer for

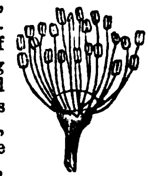
Monogynia.



Dodecagynia.

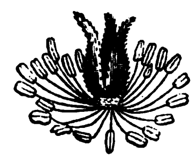
producing a yellow colour; while another, *R. odorata*, is the universal favourite, mignonette, cultivated entirely for its scent. The extensive *Euphorbia* or *Spurge* family also belongs to this class, and the curious *Sempervivum*, or house-leek, as well as the still more remarkable *Cephalotus*, whose leaves are formed into elegant pitchers, furnished with lids, like those of the *Nepenthes*, or pitcher-plant.

XII. Icosandria.—Flowers having twenty or more stamens seated upon the corolla or calyx. The situation, and not the number of the stamens, furnishes the characters of the class. This is one of the most important of the Linnæan classes, as containing many of our most useful fruits, as well as most esteemed flowers, such as the roses, the gorgeous Cactal genera, *Cereus*, *Epiphyllum*, and *Opuntia;* the myrtle, and its allied genera, *Eugenia*, and *Eucalyptus*. Of fruits we have the guava, pomegranate, pear, apple, quince, strawberry, raspberry, &c. Of the extensive genus *Mesembryanthemum*, there are many hundred species.



Monogynia.

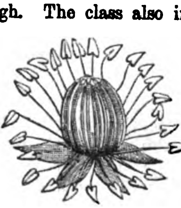
XIII. Polyandria.—Flowers having an unlimited number of stamens, distinct from each other, and seated on the receptacle. This class comprises, among many others, the caper-tree, the well-known poppy, the curious sarracenia, and the magnificent water-lily. To this class also belongs the *Bixa orellana*, the red pulp of which is extensively used by dyers under the name of arnotto;



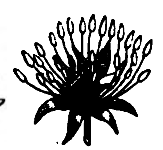
Trigynia.

Monogynia.

the splendid peony, the beautiful larkspurs, the dangerous aconite, and the butter-nut, a pleasant cooling tropical fruit, which is beginning to become known in Britain, being now offered for sale in the shops in Liverpool and Edinburgh. The class also includes a great many fine



Polygynia.

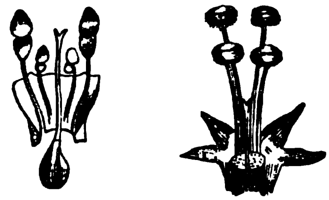


Pentagynia.

flowering-plants, both shrubs and herbs: among the former, the magnolia is most conspicuous; among the latter, the columbine, anemone, and ranunculus. Of early or winter flowering-plants, the aconite and hellebore are examples, and the globe-flower and marsh-marigold are showy plants.

XIV. Didynamia.—The flowers of this class are generally ringent; they have four stamens, *two of which are longer than the others*. The flowers of the fourth class have also four stamens, but these are of equal lengths; while in this, two are long and two short. The calyx also is of one leaf, and tubular, divided into five or two lipped segments, which are unequal and persistent. The corolla is of one petal; the upper lip concave, and sometimes bifid; the lower lip trifid. In the first order, the so-called Gymnospermæ, we find the germander, lavender, mint, and dead-nettle, and many others of similar character: several of them are useful in cookery. The order Angiospermæ, so called because, though the stamens are the same in number and position, the seeds are differently disposed, being contained in a more evident capsule than the preceding. Many of the plants in this

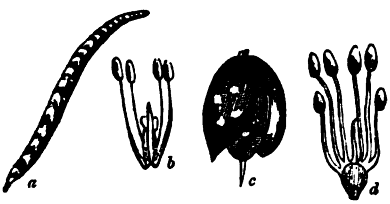
order are very beautiful; for instance, the bignonia, antirrhinum, mimulus, &c. The common foxglove



Angiospermæ. Gymnospermæ.

(*Digitalis purpurea*), so conspicuous on our hedge-banks, also belongs to this order.

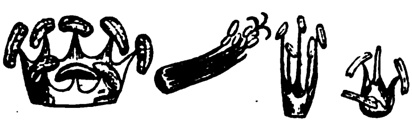
XV. TETRADYNAMIA.—Flowers with six stamens, four of which are longer than the other two. Linnæus divided this class into two orders—SILICULOSÆ and SILIQUOSÆ—the former being a short roundish pod (*c*), and the latter a long one (*a*). Many of the plants are dietetic—as the cabbage, turnip, radish, &c.; and some are finely scented and favourite flowers—as the wallflower, stock, rocket, &c. The seeds of several cruciferous plants yield oil of excellent quality. This is a truly natural class of plants, forming the *Cruciferæ* of Jussieu; great similarity of the flowers, seeds, &c., being observable throughout the whole of the genera. The calyx is four-leaved, sepals



Stamens and Seed-vessels.

concave, equal, and deciduous; corolla of four petals, claws inserted into the receptacle, limbs widening outwards in a cruciform manner.

XVI. MONADELPHIA.—The stamens are united into one set in this class, which is divided into eight orders, founded on the number of the stamens, not on that of



Octandria. Heptandria. Pentandria. Triandria.

the pistils, as in other classes. In the first order, TRIANDRIA, we find several beautiful Cape bulbs—as the *Tigridia*, *Herbertia*, &c. The flowers are not only of uncommon forms, but curiously spotted or streaked with dark colours. Of the second order, PENTANDRIA, the passion-flower is the most remarkable. There is also the *Erodium* or heron's-bill, a section of plants allied to the geraniums. The third order, HEXANDRIA, contains but one genus, a bulbous-rooted plant, called *Gilliesia graminea*, having grass-like leaves and curious flowers. The fourth order, HEPTANDRIA, contains the pelargoniums, commonly called geraniums—a genus of plants unequalled for immense variety of forms and colours. They are chiefly natives of the Cape of Good Hope. The fifth order, OCTANDRIA, having eight stamens, united in one set, contains the genus *Aitonia*, named by Linnæus in honour of the late William Aiton, Esq., royal gardener at Kew. In the sixth order, DECANDRIA, we find the true geraniums or crane's-bills, chiefly herbaceous plants, found in many parts of the temperate latitudes. The seventh order, DODECANDRIA, are all tropical plants. In the eighth order, POLYANDRIA, are many of our gayest flowering-plants—as the althea,

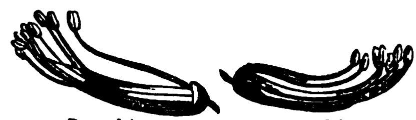
Polyandria. Dodecandria. Decandria.

lavatera, hibiscus, sida, silk cotton-tree, the tea-tree, and its magnificent congener, the camellia.

XVII. DIADELPHIA.—Flowers having two sets or brotherhoods of stamens. In general, nine are united

Hexandria. Pentandria.

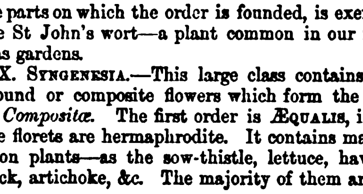
together, with a single one by itself, which is accounted the second brotherhood. Examples: *Monniera trifolia*,



Decandria. Octandria.

an African annual of no great beauty; *Fumaria*, fumitory; and *Polygala*, the milkwort; and leguminous plants. These are showy plants of curiously constructed flowers, called *papilionaceous*, or butterfly shaped; their seed-vessels being pods, such as the common furze, broom, genista, laburnum, restharrow, lupine, and many other beautiful plants, as well as trees, shrubs, and herbs.

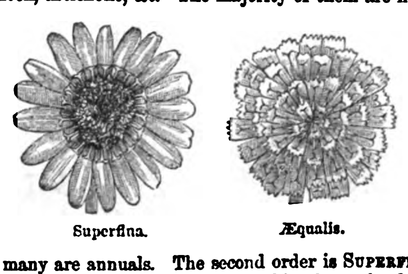
XVIII. POLYADELPHIA.—This class contains all plants whose flowers have their stamens arranged in many brotherhoods. Among the plants of this class we find the *Theobroma*, which yields chocolate. This disposition



Polyandria. Decandria.

of the parts on which the order is founded, is exemplified in the St John's wort—a plant common in our fields as well as gardens.

XIX. SYNGENESIA.—This large class contains all the compound or composite flowers which form the natural order *Compositæ*. The first order is ÆQUALIS, in which all the florets are hermaphrodite. It contains many very common plants—as the sow-thistle, lettuce, hawkweed, burdock, artichoke, &c. The majority of them are herbs,



Superflua. Æqualis.

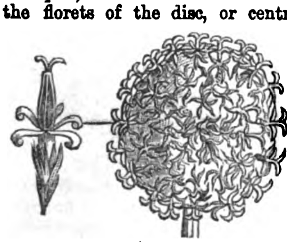
and many are annuals. The second order is SUPERFLUA; here we find plants, the flowers of which have the florets

of the disc bisexual, and those forming the rays female. This is also a very large order, and contains many useful as well as beautiful plants, of which tansy and chamomile, helichrysiums, xeranthemums, dahlias, &c., are examples. The third order is FRUSTRANEA, so called because the florets of the disc are bisexual, and those in the ray or margin neuter. To this belongs the splendid sunflower, with which many of the same style of flowering-plants are arranged, such as the rudbeckia,

Necessaria.

Frustranea.

coreopsis, &c. The fourth order is NECESSARIA, because the florets of the disc, or centre of the flower, being all male, it is necessary that those of the ray or margin should be female, in order that there may be perfect seed produced. Example: Calendula. The fifth order is called SEGREGATA, because the florets have each its proper involucre. All the plants in this order are exotic herbs and under-shrubs, the globe-thistle being the most common in British gardens.



Segregata.

XX. GYNANDRIA.—This class contains plants which have their stamens seated upon the pistil; they are generally herbaceous, with tuberous roots, curious gouty or climbing stems; many are epiphytes growing on trees.

Hexandria. Diandria. Monandria.

The class is divided into three orders; the first, MONANDRIA, having one anther seated on the pistil, and comprises orchis, ophrys, epipactis, &c. In the second order, DIANDRIA, the flowers have two anthers on the pistil; to this belongs the ladies-slipper, a great rarity found in damp woods, particularly in the north of England. The third order, HEXANDRIA, containing plants which have six stamens seated in the pistil, has only one genus—namely, the *Aristolochia*, or birthwort.

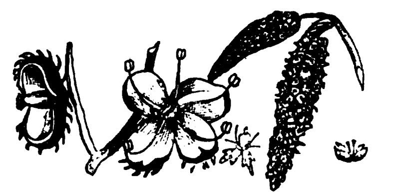
XXI. MONŒCIA.—This class consists of plants which

Diandria.

Monandria.

have male and female flowers separate, but on the same root—such as the celebrated bread-fruit tree, the *Zannichellia palustris*, the maize or Indian corn (*Zea*), the box and mulberry, the common nettle, the well-known foreigner *Aucuba japonica*, the amaranthus, the coco-nut, and other palms, *Begonia*, the chestnut, beech, hazel, walnut, oak, pines and firs, larch, cedar, cypress, &c. Here are also the gourd, melon, and cucumber, the poisonous manihot, and the castor-oil. There are ten orders, distinguished by the number and arrangement of the stamens, &c., some of which are illustrated in the wood-cuts. To this class belong the *Carices*, which form so important a feature in the Floras of cold countries, and also the *Eriocaulon septangulare*, which is interesting in a botanico-geographical point of view, inasmuch as it represents in the Western Isles of Scotland a genus which prevails on the American continent. Of *Zannichellia*, it may be observed that it would form an interesting plant for a fresh-water aquarium; and certainly no other aquatic genus requires more careful elucidation with respect

Triandria.



Pentandria. Tetrandria.

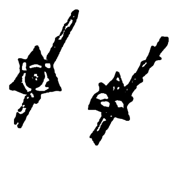
Polyandria. Hexandria.

Monadelphia.

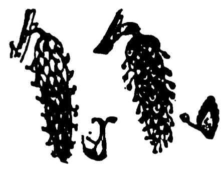
to its species. Since this sheet was in type, we have received from Benares a beautiful plant covered with large clusters of the curiously crested fruit of this genus; it appears to be an undescribed species, and has received the provisional name of *Zannichellia Spottiswoodiana*.

XXII. DIŒCIA.—This class is composed of plants which have unisexual flowers, not on the same, but on different individuals, such as the remarkable screw-pine: so called because the leaves resemble those of the pine-apple, although much larger, and they issue from the stem in a very different manner; that is, neither opposite nor alternately, but the last always a little to the left of the former, so that they are expanded spirally like the worm of a screw. Here also we have the willow,

crow-berry, date-palm, candle-berry myrtle, sweet gale, spinach, misletoe, stratiotes, &c. The orders are distinguished by the number, &c., of the stamens, as indicated in the following wood-cuts :—



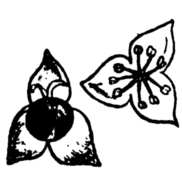
Triandria.



Monandria.

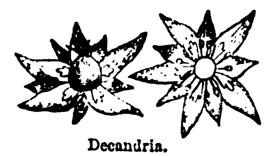
Hexandria.

Pentandria.

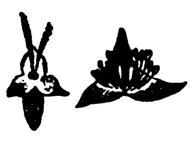


Enneandria.

Octandria.

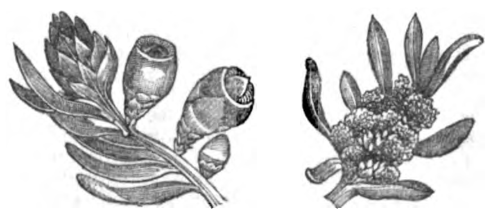


Decandria.



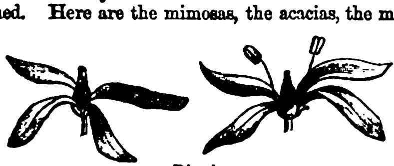
Polyandria.

Icosandria.



Monadelphia.

XXIII. Polygamia.—The class Polygamia (a word signifying many marriages) is composed of plants having both unisexual and bisexual flowers on the same or on different roots. There is considerable uncertainty about the arrangement of this division, because some of the genera are not always constant in their modes of flowering; and even single plants will occasionally exhibit all the characters by which the different orders are distinguished. Here are the mimosas, the acacias, the maples,



Diœcia.

the beautiful Ailantus, the mango, many grasses, the ash—so useful for its timber—the bread-nut, the anacardium, and figs.

XXIV. Cryptogamia.—The class Cryptogamia (a term signifying hidden marriages) consists of the flowerless plants corresponding with the class of the same name in the natural system, to which reference may be made for further particulars.

THE NATURAL SYSTEM.

'The Natural System of Botany,' says Dr Lindley, 'being founded on these principles—that all points of resemblance between the various parts, properties, and qualities of plants shall be taken into consideration; that thence an arrangement shall be deduced in which plants must be placed next each other which have the greatest degree of similarity in these respects; and that consequently the quality of an imperfectly known plant may be judged of by that of another which is well known—it must be obvious that such a method possesses great superiority over artificial systems, like that of Linnæus, in which there is no combination of ideas, but which are mere collections of isolated facts, having no distinct relation to each other. The advantages of the Natural System, in applying botany to useful purposes, are immense, especially to medical men, who depend so much upon the vegetable kingdom for their remedial agents. A knowledge of the properties of one plant enables the practitioner to judge scientifically of the qualities of other plants naturally allied to it; and therefore the physician acquainted with the natural system of botany may direct his inquiries, when on foreign stations, not empirically, but upon fixed principles, into the qualities of the medicinal plants which have been provided in every region for the alleviation of the maladies peculiar to it. He is thus enabled to read the hidden characters with which Nature has labelled all the hosts of species which spring from her teeming bosom. Every one of these bears inscribed upon it the uses to which it may be applied, the dangers to be apprehended from it, or the virtues with which it has been endowed. The language in which they are written is not indeed human: it is in the living hieroglyphics of the Almighty, which the skill of man is permitted to interpret. The key to their meaning lies enveloped in the folds of the natural system, and is to be found in no other place.' Such a system as is here eloquently delineated, we aim at rather than possess. All the modifications—and they are neither few nor unimportant—of Jussieu's original plan which have been promulgated, are merely contributions to one great end; and years of patient research, crowned by the most extensive powers of generalisation, must elapse before botany can boast of a perfect system. Passing, then, numerous recent suggestions, British and continental, we shall adhere in our brief exposition to a simple modification of the natural system which seems most applicable to botanical works now in current circulation.

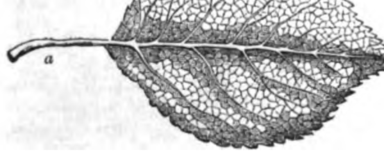
According to the original system of Jussieu, all the known plants were arranged into a hundred Orders, beginning with the *Fungi*, and mounting upwards to the *Coniferæ;* and these Orders were divided into three great Classes—namely, the ACOTYLEDONES, or plants without any cotyledon in the seed; the MONOCOTYLEDONES, plants with one cotyledon; and the DICOTYLEDONES, those with two or more cotyledons. The Acotyledonous plants were not subdivided; but the Monocotyledones were arranged into sub-classes, according as the stamens were *hypogynous*, or arising from under the pistil; *perigynous*, or growing from the calyx; and *epigynous*, or arising apparently from above the ovary by adhesion to it. The Dicotyledones were divided into the *apetalous*, or those without petals; the *monopetalous*, those with one petal; and the *polypetalous*, those with several petals; and these again were subdivided, according to the position of the stamens with regard to the pistil, in the same manner as the Monocotyledonous plants. To these were added what Jussieu called *Diclines*, or those plants with separated unisexual flowers. The fault of this system, like that of Linnæus, was that it associated species dissimilar in their nature; the classification depending on one peculiar feature more than on the general appearance, qualities, and habits of the plant.

The system of Jussieu was improved by Decandolle, who at first made 161 Orders; but these were afterwards greatly increased, and Lindley now enumerates upwards of 300.

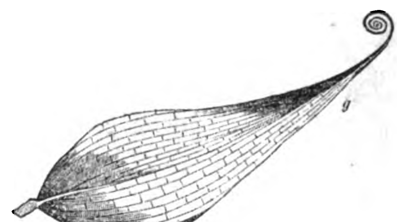
The first grand division of De Candolle, like that of Linnæus, is into the Flowering and Flowerless plants, which he designates respectively the *Vasculares* and the *Cellulares*. This division, however, is not absolutely correct; for although all the flowering-plants contain vascular tissue, and the flowerless consist principally of cellular tissue, yet spiral vessels and ducts are common in the ferns and club-mosses. The *Vasculares* and *Cellulares* of De Candolle may be considered as equivalent to the *Phænogamia* and *Cryptogamia* of the older botanists.

His second division depends upon the cotyledons of the embryo; and, like Jussieu, he divides the flowering-plants into DICOTYLEDONES, or those with two or more

cotyledons or seed-leaves, as *a*; MONOCOTYLEDONES, those which have only one seed-leaf (*b*, *b*); and ACOTYLEDONES, those having no seed-leaf, and, in fact, no seeds—such as the Cryptogamia. The differences between these three divisions are decided, and are exhibited in different parts of the plant; but they are particularly conspicuous in the leaves—the venation of Dicotyledonous

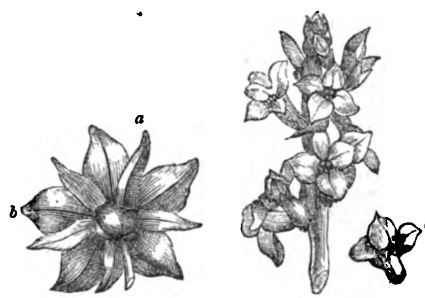


leaves being reticulated, as in the apple (*a*); and that of Monocotyledonous being chiefly in parallel lines, as shewn in the leaf of the Gloriosa (*g*). Dicotyledonous trees are said to be *Exogenous*, from the fact of their



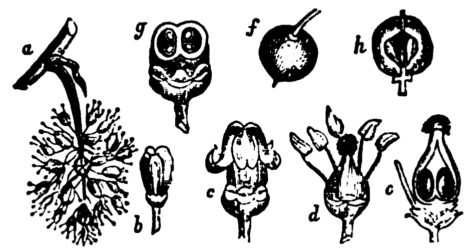
trunks increasing by external layers; Monocotyledonous ones, *Endogenous*, on account of the enlargement taking place from within; and Acotyledonous trees, *Acrogenous*, because the increase takes place only at the top or growing-point.

Dicotyledonous plants are divided into the *Dichlamydeæ*, or those with two floral envelopes—that is, having



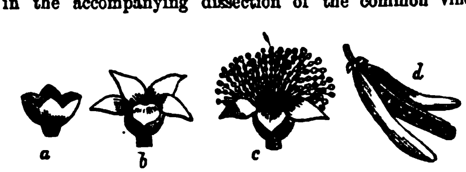
a separate calyx (*a*) and corolla (*b*); and the *Monochlamydeæ*, or those having only one floral envelope, which is always called the calyx, as in the detached floret in the wood-cut (*c*). These distinctions, however, are not always invariable, as many plants in the first division have no corolla, but simply a coloured calyx.

The *Dichlamydeæ* are further divided into three sub-classes:—I. *Thalamifloræ*, in which the stamens and



Vine.—*a*, bunch of flowers; *b*, flower before expansion; *c*, flower expanding; *d*, stamens and ovary; *e*, vertical section of the ovary; *f*, fruit; *g*, horizontal section of the ovary; *h*, vertical section of the fruit, shewing the position of the seed.

petals are all inserted in the receptacle, as represented in the accompanying dissection of the common vine.



Acacia.—*a*, calyx; *b*, corolla; *c*, flower; *d*, seed-pod open.

II. *Calyciforæ*, in which the stamens and petals are

perigynous, inserted in the calyx, as shewn in the preceding dissection of an acacia; or epigynous, arising from the upper part of the ovary. III. *Corolliflorœ*, in which the stamens are inserted on the petals, as in the annexed dissection of the acanthus, or in a few cases on the

Acanthus.—*a*, corolla opened, shewing the stamens and pistil; *b*, one stamen; *c*, pistil; *d*, ripe seed-vessel, covered with its calyx and bracts; *e*, seed-vessel burst previously to shedding its seeds; *f*, seed opened, shewing the radicle and plume.

receptacle, the parts of the corolla being united together. The *Monochlamydeœ* are those having only one floral envelope.

Monocotyledonous plants are divided into those with petals, called *Petaloideœ*, and those with glumes, like the oat, *Glumiferœ*.

Flowerless or *Cryptogamous* plants are divided into two classes—those formed of a cellular expansion without distinct stem or leaves, which are called *Thallogens* (*a*); and those with leaves borne upon a distinct stem, *Acrogens*.

Cryptogamous plants.

The distinctions between the orders are drawn from the number and arrangement of petals, sepals, and stamens; the construction of the anthers, and the manner in which they burst; the structure of the seed-vessel and of the seeds, with the position of the embryo; the position of the leaves, whether alternate or opposite, or with or without stipules; and the general habits and properties of the plants.

Having thus explained the basis of arrangement, we shall now proceed to consider the ORDERS—premising that while the whole are tabulated, our space will only permit us to detail the more interesting and important ones. This, however, we shall endeavour to do in such a manner as may at once present an outline of the System, and render the reader familiar with the phraseology and plan of procedure.

In this and the subsequent lists of natural orders, those orders marked with an asterisk contain British representatives.

DICOTYLEDONOUS PLANTS.—DICHLAMYDEÆ.

§ THALAMIFLORÆ.

*Ranunculaceæ—Crowfoots.
Dilleniaceæ—Dilleniads.
Magnoliaceæ—Magnoliads.
Anonaceæ—Anonads.
Schizandraceæ—Schizandra order.
Menispermaceæ—Moonseeds.
Lardizabalaceæ—Lardizabala order.
*Berberidaceæ—Berberids.
Cabombaceæ—Watershields.
*Nymphæaceæ—Water-lilies.
Nelumbiaceæ—Water-beans.
Sarraceniaceæ—Sarraceniads.
*Papaveraceæ—Poppyworts.
*Fumariaceæ—Fumeworts.
*Cruciferæ—Crucifers.
Capparidaceæ—Capparids.
*Resedaceæ—Weldworts.
Flacourtiaceæ—Bixads.
*Cistaceæ—Rock-roses.
*Violaceæ—Violets.
*Droseraceæ—Sun-dews.
*Polygalaceæ—Milkworts.
Krameriaceæ—Rhatany order.
Tremandraceæ—Poreworts.
*Tamaricaceæ—Tamarisks.
*Frankeniaceæ—Frankeniads.
*Elatinaceæ—Water-peppers.
*Caryophyllaceæ—Cloveworts.
Vivianiaceæ—Vivania order.
*Malvaceæ—Mallowworts.
Sterculiaceæ—Silk-cottons.
Byttneriaceæ—Byttneriads.
*Tiliaceæ—Lindenblooms.
Dipteraceæ—Dipterads.
Chlænaceæ—Chlænads.
Ternströmiaceæ—Theads.
Olacaceæ—Olacads.
Icacinaceæ—Icacina order.
Cyrillaceæ—Cyrilla order.
Aurantiaceæ—Citronworts.
*Hypericaceæ—Tutsans.
Guttiferæ—Guttifers.
Marcgraviaceæ—Margraviads.
Hippocrateaceæ—Hippocrateads.
Malpighiaceæ—Malpighiads.
Erythroxyleæ—Redwoods.
*Aceraceæ—Maples.
Sapindaceæ—Soapworts.
Rhizobolaceæ—Rhizobols.
Meliaceæ—Meliads.
Humiriaceæ—Humirium order.
Cedrelaceæ—Cedrelads.
Vitaceæ—Vineworts.
*Geraniaceæ—Cranes-bills.
*Linaceæ—Flaxworts.
*Oxalidaceæ—Oxalids.
*Balsaminaceæ—Balsams.
Tropæolaceæ—Indian Cresses.
Limnanthaceæ—Limnanths.
Pittosporaceæ—Pittosporum order.
Brexiaceæ—Brexia order.
Zygophyllaceæ—Bean-capers.
Rutaceæ—Rueworts.
Xanthoxylaceæ—Prickly-ash order.
Ochnaceæ—Ochnads.
Simarubaceæ—Quassiads.

RANUNCULACEÆ.—The plants constituting this order are herbs, or rarely shrubs, with deeply cut, rarely stipulate leaves, and stem-clasping petioles. The majority of the species are hardy, and abound in an acrid poisonous juice, as is well exemplified in the common butter-cups of the meadows belonging to the genus *Ranunculus*, from which the order takes its name. The plants of the order are very variable in their flowers; many of them having merely one floral envelope, and others having a coloured calyx, with only very small and inconspicuous petals. When the flowers are regular—that is, when the parts are all of one size—the corolla consists generally of five petals, and the calyx of five sepals, though the number of the petals sometimes varies from three to fifteen. There are numerous stamens which grow from beneath the pistil, and are always separate, having their anthers bursting outwardly. The seeds are for the most part contained in carpels which grow close together. The embryo is very small, and placed at the base of the albumen, which is either fleshy or bony. In consequence of the variable character of their flowers, the Ranunculaceæ are somewhat perplexing to the learner, though they may be generally known by their numerous distinct stamens springing from below the pistil, and by their distinct carpels, which frequently grow in several whorls round an elevated receptacle, as in the crowfoot and *Flos Adonis*. The calyx generally falls off with the petals, but in the peony it remains till the seed is ripe. The carpels are in many cases only one-seeded, and are sometimes winged, as in the anemone and clematis, in order to scatter the seeds, as the carpels in this case do not open naturally, but fall with the seed. Sometimes, however, the carpels are many-seeded, and open naturally when ripe, as in the peony, the larkspur, the columbine, &c. The principal genera—which lie within the examination of every one—are the Ranunculus and Peony, having regular flowers and two floral envelopes; the Anemone, the Hepatica, the Christmas Rose, and the winter Aconite, which have regular flowers, but generally only one floral envelope; and the Larkspur, Monkshood, and Columbine, which have irregular flowers. The Clematis is one of the few shrubby plants belonging to the order; it has regular flowers, and generally only one floral envelope. The Ranunculaceæ are of little

economical importance. The juice of the whole order is acrid, the roots of many intensely bitter, and the bark of a few tonic and bitter. The seeds of the Nigella are aromatic, and were formerly used as pepper; but those of all the other genera are poisonous, unless husked. The flowers of some are objects of great beauty—as the larkspurs, ranunculuses, anemones, peony, and columbine. The 'lesser celandine' of Wordsworth (*Ranunculus Ficaria*) has been used as an article of food in Austria, its small farinaceous tubers resembling pease. But most of the plants belonging to the order are acrid and poisonous, some of them eminently so. *Ranunculus arvensis* is one of the most dangerous farm-weeds which the agriculturist has to fear; but the monkshood (*Aconitum Napellus*) exceeds them all in virulence, and has been the cause of distressing accidents, from its root being mistaken for horse-radish, &c. We read in classic story how the Roman stepmothers of old employed this root to poison their adopted children; and a nearly allied species has derived notoriety from having been employed by the Nepalese to poison their wells against the approach of an enemy. According to Mr Herapath, the poisonous alkaloid of the monkshood (Aconitine) is the most deadly poison known.

DILLENIACEÆ.—This order consists of woody plants, having astringent qualities. Some of them yield excellent timber. They are chiefly confined to Australasia, India, and equinoctial America.

MAGNOLIACEÆ.—This order consists of woody plants, remarkable for the beauty of their flowers and foliage, of which the common magnolia of gardens is a familiar example: they have bitter, tonic, and aromatic qualities. The New Holland tree called *Tasmannia aromatica*, supplies a substitute for pepper, Winter's Bark is yielded by *Drimys*, and the tulip-tree of North America is the *Liriodendron tulipifera*. The wood of *Illicium* and *Drimys* exhibits under the microscope an appearance of discs slightly resembling those of Coniferæ.

ANONACEÆ.—Woody plants, chiefly natives of the tropical regions. The sweetsop, soursop, and custard-apple, are yielded by species of *Anona*. The lance-wood used by coachmakers is supposed to be yielded by another plant of this order (*Duguetia quitarensis*).

SCHIZANDRACEÆ.—The plants of this order are chiefly trailing tropical shrubs, abounding in an insipid mucus. The fruit of some is eatable, but the order is otherwise unimportant.

MENISPERMACEÆ.—Trailing herbs or shrubs, climbing to the tops of the highest trees in hot countries, their stems formed by peculiar woody wedges. *Cocculus Indicus*, a dangerous substance, which appears to be extensively employed in the adulteration of malt liquors—chiefly the cheaper sorts—consists of the berries of *Anamirta paniculata*, a plant of this order which abounds on the Malabar coast and in the Indian Archipelago. Its use for such purposes is forbidden by act of parliament; but as 2359 hundredweights were imported into Britain in 1850, it appears pretty certain that it finds other uses than that of medicine. The bitter tonic calumba root is derived from *Jateorrhiza palmata*.

LARDIZABALACEÆ.—An unimportant order, consisting of fifteen twining shrubs, which are distributed over the cooler parts of South America and China; the fruits of some are eatable.

BERBERIDACEÆ. — Plants of temperate and warm countries in both hemispheres, represented in Britain by the common barberry of our hedgerows, the stamens of which display the phenomenon of irritability when touched near the base by the point of a pin. According to Professor Simpson, the roots of several species furnish the astringent matter called Lycium by Dioscorides.

CABOMBACEÆ consists of three aquatic plants, with floating peltate leaves, occurring in America and New Holland.

NYMPHÆACEÆ.—Gigantic aquatic herbs, with a thick rhizome in the mud, giving off large floating leaves on long petioles. The rhizomes exhibit a structure resembling that of endogenous plants; but the embryo is truly dicotyledonous. Water-lilies appear to occur in most parts of the world, except cold regions. The white water-lily (*Nymphæa alba*) is one of the greatest ornaments of the English and Scotch lakes; while the yellow one (*Nuphar lutea*) more commonly occurs in slow streams and pools. *N. pumila* is rare. More magnificent than all is the *Victoria regia*, the royal water-lily of South America, whose size, in keeping with the gigantic proportions of the Amazons and Essequibos, on whose waters it displays its beauty, is unrivalled in the vegetable kingdom. Its floating leaves are two yards across, continuously covering miles of surface with their verdure, each having a turned-up margin like a tea-tray. The flowers are a foot across, formed of hundreds of petals of the most delicate rose-colour, and exhale a delicious perfume in the evening as they expand. This plant has been successfully cultivated in the public gardens of London, Belfast, Glasgow, &c.

NELUMBIACEÆ.—This order, consisting of the Water-beans of the tropics, is chiefly remarkable, in a structural point of view, on account of the large torus, in which the nuts are half buried, resembling the rose of a watering-pan. *Nelumbium speciosum* is that 'mythic lotus'—the 'holy and beautiful plant'—which is sculptured on the ancient monuments of Egypt and India, and before which the Hindoos prostrate themselves to this day.

SARRACENIACEÆ. — The plants of this order have hollow pitcher-shaped leaves, in which insects are entrapped. They chiefly occur in the North American swamps.

PAPAVERACEÆ.—This order consists of very handsome herbaceous plants, annual and perennial, most of which are natives of the temperate parts of Europe and Asia. The leaves are alternate, sometimes deeply cut, and without stipules. The flowers are solitary, elevated on long peduncles, showy, and usually white, yellow, or red; and the bud in all, except the large scarlet Eastern poppies, is shrouded in only two sepals, which fall off as soon as the flower expands. The Oriental species have three sepals, and one of them (*Papaver bracteatum*) has two large bracts which remain after the flower has expanded, and form a kind of calyx, though the real calyx has dropped off. There are generally four petals, or a multiple of four, which are crumpled in the bud, and soon fall off. The stamens are very numerous, inserted in four or more bundles beneath the pistil (*a*). The ovary is solitary, forming a capsule, which consists of several carpels grown together; stigmas generally stellate on the flat apex of the ovary. Notwithstanding the fleshy ovary, the fruit is a dry capsule, with only one cell, the divisions between the carpels having disappeared. The seeds are numerous, have a minute straight embryo, imbedded in albumen, and become loose in the capsule when they are ripe. Before the seeds are ripe, the walls of the capsules become as hard as a shell; and the stigmas, which are grown together, and become equally hard, form a star-shaped lid for the capsule (*b*). Under this there

P. somniferum.

is a set of valves that open for the discharge of the seed.

The British genera are—*Papaver*, the poppy, of which there are many species; *Meconopsis*, the Welsh poppy; *Glaucium*, horned poppy; *Chelidonium*, greater celandine or swallowwort. There are many more, however, grown in our gardens as ornamental plants, such as *Sanguinaria*, or blood root; *Argemone*, the prickly poppy; *Eschscholtzia; Hunnemania; Rœmeria; Hypecoum; Platystemon;* and *Platystigma*. In the horned poppy, which is common on the south-east coast of England, and of occasional occurrence in Scotland, the seed-vessel is formed of only two carpels grown together, which look like a pod; and when ripe, from their length and stiffness, bear a considerable resemblance to a horn; hence the name. The greater celandine, as well as the prickly poppy, has a yellow juice—the juice of the others is white. In the Eschscholtzias the sepals do not separate; but becoming detached at the base, they retain the shape of a hood or extinguisher, till pushed off by the expansion of the corolla. The capsules of the Eschscholtzias are elongated, and are easily known by the large fleshy projection at their base. The plants of the order are easily detected by their general resemblance to each other, especially in their flowers, with the exception, perhaps, of the celandine, the flowers of which are small.

All the Poppyworts abound in a thick glutinous juice, which poisons by stupifying. All parts of the plant furnish more or less this milky sap, but the main supply is derived from the unripe seed-vessels. When in a green state, those of the large white poppy (*P. somniferum*) are slightly wounded with a knife, which causes the juice to exude freely; and on exposure to the air, it concretes or becomes inspissated. In this state it forms crude or lump opium, which, dissolved in spirit of wine, and filtered, produces the laudanum of the shops. Chemically, opium consists of an insoluble gum, a small quantity of resin, and caoutchouc. Its effects on the animal system depend upon two alkaline principles which it contains—namely, morphia and narcotine; the former producing a sedative, and the latter a stimulating effect. It is curious that the seeds possess none of the stupifying properties of the plant, but are mucilaginous and oily, and may be eaten with impunity. The seeds of one species, however (*Argemoné Mexicana*), are said to be narcotic, especially when smoked; but it is probable that in this case the opiate resides in the coating of the seed rather than in the albumen.

Fumariaceæ.—These plants indicate relationship with the preceding order in their two deciduous sepals, and with the following in their cruciate petals; but their habit is quite peculiar, the leaves much cut, often glaucous, and the juice watery. The Fumeworts, so common in hedges and cultivated places, are familiar examples, and their curious flowers deserve attention. When large, they are showy, as in *Diclytra spectabilis* (Chinaman's Breeches), a plant which, although only of recent introduction from China, is already one of the pets of cultivators, occupying equally the cottage-garden and the palace conservatory.

Cruciferæ.—This is one of the most extensive and important of the natural orders. Most of the genera are herbaceous annuals and perennials. The leaves are alternate, and the flowers are produced in corymbs or racemes, being usually regular, with a calyx of four sepals, and a corolla of four petals, disposed in the form of a Maltese cross: hence the name *Cruciferæ*, or cross-bearing. There are six stamens, two much shorter than the others, as shewn under the Linnæan class *Tetradynamia*. The pods open naturally when ripe, the valves curling outwards, as in the common cabbage or turnip, for example. The seeds have no albumen, and the cotyledons are curiously folded down on the radicle. There can be no difficulty in recognising a cruciferous plant when it is in flower, by the cross-form of its corolla, as in the preceding figure, and its six stamens, two of which are shorter than the others.

Crucifer.

Among the more common genera may be mentioned *Brassica*, including the cabbage; *Cheiranthus*, the wall-flower; *Mathiola*, the stocks; *Iberis*, the candy-tuft; *Isatis tinctoria*, the woad; *Cochlearia*, the horse-radish; *Sinapis*, the mustard; and many other well-known plants. Most of them are natives of Europe; but plants of the order, which contains about 170 genera, are found in every part of the world.

The properties of the Crucifers are antiscorbutic and stimulant, combined with an acrid flavour; and the seeds of many abound in a fixed oil: properties of which the common cress, mustard, and rape may be taken as examples. Most of them form articles of human food, and are valuable not only for their antiscorbutic properties, but from the fact that they contain a large amount of nitrogen. All the cultivated varieties of turnip appear to have been derived from *Brassica Rapa*, which occurs in a wild state in Britain. *Isatis indigotica* yields a kind of indigo.

Capparidaceæ.—This order—represented by *Capparis spinosa* of Southern Europe, whose flower-buds are the capers of commerce—is nearly allied to the preceding, but well distinguished by the usually indefinite (numerous) stamens, which are never tetradynamous.

Resedaceæ.—The chief genus is Reseda, to which our sweet mignonette belongs. Flacourtiaceæ is likewise a comparatively small order, one of its plants, Bixa, yielding arnotto, a red dye, which is also used in the manufacture of chocolate. Droseraceæ is chiefly remarkable on account of the glandular hairs on the leaves of our British species which are called Sundews. Venus's flytrap has more irritant leaves. (See Vegetable Physiology, p. 77.)

Malvaceæ.—This is a very marked and natural order, all the plants belonging to it bearing a striking resemblance to each other, and remarkable for their large showy flowers. The petals and sepals are each five in number, but the calyx has three bracts on the outside, which are frequently so near to it as to have the appearance of a second calyx below the true one. Estivation twisted. The most remarkable part of the flower is the central column, and this is so decided, that a botanist is always able to recognise one of the Malvaceæ at first sight. This column is formed by the filaments of the stamens growing together, so as to leave only a small portion just below the anthers free, as is seen in the flower of the marsh-mallow—the lower portion forming a tube round the pistil. The anthers themselves are also peculiar: they are one-celled, kidney-shaped, and burst transversely, opening inwardly. This peculiar construction of the stamens may be observed distinctly in the Lavateras, the hollyhocks, and, in short, in all the genera belonging to the order. The styles also grow together, as may be seen when the stamens are removed; and the carpels, which are of the same number with the styles, form what children call 'mallow cheeses.' The carpels are one or many seeded, sometimes closely united, sometimes separated or separable; fruit capsular or baccate. Most of the species are herbaceous plants; several, trees or shrubs. Leaves alternate, more or less divided and stipulate, often covered with stellate hairs.

Marsh-mallow.

All the plants possess showy flowers, abound in

mucilage, and are destitute of unwholesome qualities. It will be seen that there is a considerable resemblance between the flax and the mallow tribes. Both possess mucilaginous qualities; in both the parts of the flower are in fives; and in both the filaments of the stamens are partially united: though in the flax the union is only at the base, whereas in the mallows it is carried up so as to form the central column, which is so marked a feature of the order. The herbaceous species of the Malvaceæ have woody fibre in their stems, but not in such abundance as in the common flax. The one-celled anther of the mallows, and the central column, are, however, the striking marks of distinction. Plants belonging to the order are found in almost every part of the world, but the cotton-plant (*Gossypium*) will only thrive in hot climates.

The economical uses of the order are highly important. Cotton, on which so much of British commerce depends, is obtained from several species of *Gossypium*, and is the downy hairs which are attached to and envelop the seeds. These hairs, originally of a cylindrical form, at maturity become collapsed into flat bands, and are much twisted. Much confusion exists in botanical works relative to the species of Gossypium, the varying character of the plants having, it is feared, given rise to unnecessary names. The recent researches of Royle seem to indicate that all the forms known in commerce should be reduced to four species of plants—namely, 1. *Gossypium herbaceum*, which is the common cotton-plant in India, and a variety of which, with buff-coloured hairs, supplies the Nankin cotton. 2. *G. arboreum*, the tree-cotton of India, with red flowers and a fine silky cotton. 3. *G. Barbadense*, Barbadoes cotton, called in India Bourbon cotton, which supplies the highly esteemed Sea Island cotton, as well as the Georgia and New Orleans cottons. 4. *G. Peruvianum*, Cavanilles (or *G. acuminatum*), which supplies the Pernambuco or Brazil cotton. The great difference in the value of different kinds of cotton depends chiefly upon the length of staple, precise measurements of which have recently been published by the United States government. There are also great differences, however, in the cleaning of the cotton brought into market, neglect of which has greatly depreciated the value of Indian cotton.

Cotton is not the only textile substance supplied by this family. 'Sunn hemp,' and numerous other fibres, are obtained in tropical countries from the stems of plants of this order, and even the hollyhock of our gardens has recently been introduced under a patent process for the manufacture of cordage and paper. The Malvaceæ thrive chiefly in warm latitudes, but are not uncommon in cold countries, and one beautiful species of *Sida* rises to an elevation of from 13,000 to 15,000 feet on Pichincha.

Many of the Malvaceæ are also medicinal and dietetic. The *pâte de Guimauve*, which is made from a species of marsh-mallow, is much used on the continent in all disorders of the lungs; from the *Althæa officinalis* is prepared, in France, the vegetable tracing-paper known by the name of *papier végetale;* and a blue matter, not inferior to indigo, is said to be obtained from the leaves of the hollyhock (*A. rosea*). The native ladies in India blacken their eyebrows with the flowers of *Hibiscus Rosa Sinensis*, and Europeans apply it to the less honourable purpose of blacking their shoes.

STERCULIACEÆ is an order chiefly remarkable from containing the celebrated baobab, one of the largest trees in the world, its trunk often attaining a circumference of ninety feet. BYTTNERIACEÆ contains the *Theobroma Cacao*, or food of the gods, the seeds of which are the 'cocoa nibs' of commerce, and are employed in the manufacture of cocoa and chocolate; the latter containing in addition sugar, vanilla, cinnamon, and arnotto. This cocoa has, therefore, no connection with the coco-nut, with which popular opinion, misled by similarity of name—and a constant misspelling of the word *coco*—so constantly associates it. TILIACEÆ, represented by the lime-trees in Britain, contains several useful plants, the most important of which is *Corchorus capsularis*, which furnishes the fibre called jute, of which rice-bags are made in warm countries, and carpets in cold ones.

TERNSTRÖMIACEÆ.—This is one of the most interesting natural orders, as, besides other fine plants, it contains the camellias and tea-trees. All the members are trees or shrubs, with very handsome flowers. The leaves are alternate, and without stipules; they are frequently leathery, and are sometimes marked with pellucid dots. The flowers have generally five sepals and five petals; sometimes there are two additional sepals a little below the others. The stamens are numerous, and either grow together into a central column, or are in five distinct bundles. There are but few seeds, which are large, and entirely filled with an embryo having thick cotyledons like the bean, and no albumen.

Only a very few genera belonging to this order have been introduced into this country; but there are a number of equally beautiful species found in the East Indies and South America. Those best known in Britain are the genera *Gordonia*, *Stuartia*, *Camellia*, and the *Tea-tree*. The common camellia—*C. Japonica*—is too well known to need any description, and its beautiful flowers and thick glossy leaves must be familiar to every one. The double varieties are numerous, but the 'old double white,' as it is called, is still the favourite kind for ball-room decoration. The tea-tree is very nearly allied to the camellia, but its flowers and leaves are smaller. The teas of commerce are obtained from two different plants, named respectively *Thea Bohea* and *Thea viridis*, on the supposition that the former produced our ordinary black teas, while the latter afforded *green* tea. It would appear, however, from Mr Fortune's recent researches, that both kinds of tea are manufactured from either plant, the difference mainly depending on the time of gathering and the mode of preparation. The young leaves, quickly dried and subjected to a particular kind of manipulation, form green tea; while the older ones, dried more slowly, and undergoing fermentation, constitute black tea; but in some cases the green colour is imparted by means of a mixture of turmeric, prussian-blue, and gypsum. Teas are sometimes perfumed and flavoured by the addition of the flowers of the fragrant olive and other plants.

Long confined to China, this branch of Oriental agriculture has at length been successfully introduced to the Himalayan possessions of the East India Company. The Assam Tea is furnished by a larger plant than either of the preceding, which is said to be a distinct species.

AURANTIACEÆ.—The golden fruit of the orange and lemon, so characteristic of this order, is so beautiful,

Lemon.

that it is supposed to have been typified by the celebrated apples of the Hesperides. The order consists

of elegant and fragrant trees or shrubs. The leaves, though apparently simple, are called compound by botanists, because they are articulated with the petiole, which in the orange and some other species is winged. The calyx is tubular, with five short teeth. The petals of the corolla are five in number, thick and fleshy, and when held up to the light, they appear full of pellucid dots, which are receptacles of secretion filled with fragrant oil. There are generally twenty stamens, which are divided into five bundles, the filaments in each bundle adhering together. The fruit—hesperidium, as it is called by botanists—is divided into numerous cells by dissepiments, and there is a central placenta, to which the ovules are attached in the ovary; but as the fruit swells, the seeds become detached, and the cells fill gradually with cellular tissue, till at last they become replete with an acid and bitter pulp, in which the seeds are immersed. The seeds are exalbuminous, and sometimes contain more than one embryo.

The most familiar genus is Citrus, the species of which are chiefly natives of the tropics—most of them being found in a wild state exclusively in the East Indies. The orange, however, appears to have an extraordinary facility of adapting itself to any country the climate of which is dry and sunny; and thus have arisen the orange groves of St Michael and of Florida, besides those of Malta, and various parts of Europe and North Africa. All the kinds of orange, lemon, shaddock, citron, &c., belong to the genus *Citrus*. *C. Aurantium* is the sweet orange, so generally cultivated. The principal kinds are the common orange, the Chinese or Mandarin, the Maltese, and the St Michael. *C. medica* is the citron; *C. Limonum*, the lemon; *C. Limetta*, the sweet lime; and *var. Bergamia*, the bergamot; *C. Paradisi*, the forbidden fruit; and *C. decumana*, the shaddock. The Wampee, the fruit of *Cookia punctata*, is much admired in China and the Indian Archipelago, but does not appear to have been introduced into Europe.

All the Aurantiaceæ abound in a fragrant oily matter, which is contained in the receptacles of secretion in the rind of the fruit, and in the leaves of the tree. The pulp of the fruit is more or less acid, and is used either in its natural state, or medicinally in various forms. About 35,000 tons of oranges are said to be annually imported into Great Britain. The productiveness of the common orange is enormous: a single tree at St Michael has been known to produce 20,000 oranges fit for packing, exclusively of the damaged fruit and the waste, which may be calculated at one-fifth more.

GUTTIFERÆ.—Woody plants, with opposite, entire leaves, numerous stamens, often united, seeds exalbuminous, often immersed in pulp. These plants occur in humid localities in the tropics. The East Indian resin, called Tacamahac, is furnished by *Calophyllum Calaba*, while the *Mammea Americana* affords the mammee apple or wild apricot of South America. One of the finest of known fruits—the mangosteen—also belongs to this order. Gamboge is obtained from different species of Garcinia and Cambogia—the best kind, it is said, being that moulded in the hollow stems of bamboo.

ACERACEÆ.—This order consists of about sixty species, all of which are trees natives of temperate climates. The leaves are opposite, and without stipules; they are generally large and handsome, with five or seven lobes, though the *Negundo*, or box-elder, has the leaves pinnate. The flowers are small, but pretty, being in long drooping racemes or corymbs. The male and female flowers are distinct. The stamens, which are eight in number, are the only conspicuous part of the flower, as the petals are frequently wanting. The bracts are large and leathery, and generally roll back when the flowers expand. Most people have seen the fruit, or *keys*, as they are called, of the sycamore and maples, the botanical term for which is *samara*. This kind of fruit consists of two cells joined together on one side, each having a long membrane-like wing. There is usually only one seed in each cell; the embryo has two, and sometimes three, large thin cotyledons, which are curiously folded up, and fill the whole seed. This is rather a remarkable feature of structure, as where there is no albumen, the cotyledons are for the most part fleshy.

The genus *Acer* comprehends all the maples and the sycamore. *Negundo* is easily distinguished from the maples by its compound leaves, which resemble those of the ash. The male and female flowers of this genus are developed on different trees, being very inconspicuous. The common maple (*A. campestre*) and the sycamore, or 'plane-tree,' as it is called in Scotland (*A. pseudo-platanus*), are the only members of the order natives of Britain, though a number of other species have been introduced by culture. The Negundo belongs to America.

The sap of the maples is remarkably sweet, and sugar is frequently made in America from that of *A. saccharinum*. Indeed, the sugar-maple may be said to be a rival of the sugar-cane, the United States alone producing not less than 10,000,000 pounds per annum. The timber of the maples and sycamore is remarkably light and close-grained, and therefore much used in veneering and inlaying. The bark is astringent, and yields the dyer reddish-brown and yellow colours.

SAPINDACEÆ.—The Soapworts are woody, rarely herbaceous plants, with usually compound leaves and unsymmetrical flowers, most of them being found in the hot parts of India and America, and little known in Europe, except from the writings of travellers. This remark will not apply, however, to the *Hippocastaneæ*, or horse-chestnuts (distinguished by their opposite leaves, and by the ovary having two ovules—one erect, the other suspended—in each cell), which are natives of Northern India, Persia, and the American States. This section consists of only two genera—namely, *Æsculus*, the horse-chestnut; and *Pavia*, the scarlet-flowering chestnut. The species are all trees and shrubs, natives of temperate climates. The leaves are palmate—that

Æsculus Hippocastanum.

is, divided into five or seven parts; and are without stipules. The flowers are produced in large panicles or racemes; and are very handsome. There are five petals, two of which are smaller than the others, and all have small claws. In the scarlet horse-chestnut, and some other kinds, there are only four petals; and in the *Pavia*, two of the petals are so much smaller than the others as to look like leafy stamens. There are seven stamens, three of which are much shorter than the others The fruit of the horse-chestnut consists

of a leathery husk, which opens when it is ripe into three valves. The husk of Pavia is smooth. The scar of the hilum is very strongly marked on the testa of the nuts of both genera; and in Pavia it is so conspicuous as to give rise to the American name of the genus, which is called *Buck's-eye*, from the resemblance of the hilum to the pupil of an eye. When the seed is put into the ground, the cotyledons only open sufficiently to allow the escape of the plumule and the radicle. The plumule is very large, and has two leaves in the seed; and the radicle is close to the hilum, where of course is also the foramen. There is no albumen, the nourishment for the young plant being laid up in the thick fleshy cotyledons.

The horse-chestnuts, which belong originally to the north of India, have been so long cultivated in Europe, as now to spring up like natives of the soil. The Pavias are all natives of North America. Both of the genera are amongst the finest of our flowering-trees, and on this account are common in park-scenery. The seeds of the order abound in starchy and in saponaceous matter. The bark of the common *Æsculus Hippocastanum* is bitter, astringent, and has been recommended as a valuable febrifuge in intermittent and other fevers.

VITACEÆ.—This order comprises about 260 species, natives of temperate climates. Their prevailing habit is a long dangling growth of stem, thyrsus of colourless flowers, with tendrils opposite the leaves, and bunches of berried fruit. The stem and branches are furnished with tumid articulated nodes; the leaves are lobed or compound, generally alternate with stipules. The flowers are small, often the male and female distinct; calyx, very small; sepals and petals, four or five, the latter sometimes cohering at the tips, and falling off before the bursting of the anthers; stamens, equal in number to the petals, and opposite to them; ovary, two-celled; fruit, a berry, with the seeds immersed in pulp; seeds with a bony testa; albumen, hard; embryo, small. The curious formation of the flower and berry is well illustrated by the dissection of the common vine, as shewn in page 88.

The genera are—*Ampelopsis*, the vine-leafed ivy; *Vitis*, the grape-vine; *Leea*, *Cissus*, *Pterisanthes*, and *Rhaganus*. With the exception of the vine, the other genera are of little interest, being employed only as ornamental creepers. *Leea* is considered by some to be nearly allied to the Meliaceæ, forming as it were a connecting-link between the two orders.

The properties of the grape, either in its fresh state or dried to form raisins, or expressed and fermented to form wine, &c., are too well known to require description. The average import of raisins to Britain amounts to 12,000 tons, the finest being the Muscatel. The dried currants of commerce—a corruption of Corinths—are the produce of the small seedless Corinthian grape, which is cultivated in many islands of the Mediterranean. Currants are annually imported to the extent of 21,000 tons. *Vitis vulpina* is a kind of wild vine which produces what are called fox-grapes in North America; it forms an ornamental creeper, being hardy in Britain; and has recently attracted notice as likely to form a good stock on which to graft our grape-vines. The ravages of the grape-blight, which has of late years spread devastation over the wine-countries, might be thus in great measure prevented. (See THE FRUIT GARDEN.) The Kangaroo Vine of Australia, which is well suited as an indoor window-creeper, is a species of *Cissus*. The berries of the Virginian creeper (*A. hederacea*) are small and unpalatable, but might be eaten with perfect safety. According to Von Martius, the leaves and fruit of *C. tinctoria* abound in green colouring-matter, which soon becomes blue, and is highly esteemed by the natives of Brazil as a dye for cotton fabrics. Acid leaves, and a fruit like that of the common grape, are the usual characters of the order.

GERANIACEÆ.—The *Geraniaceæ* comprise only five genera, but about 500 species. They are herbs or shrubs, with stems which are tumid and articulated at the joints. The leaves are generally lobed, and furnished with small stipules. Calyx persistent in five-ribbed sepals. Corolla generally five-petalled, with strongly marked veins. Stamens twice as many as the petals; filaments united at the base. Fruit consists of five elastic one-seeded carpels, adhering to an elongated central axis, from which they part with an elastic jerk when ripe. Seed without albumen; cotyledons rolled up or folded.

The chief genera are *Geranium*, *Pelargonium*, and *Erodium*, respectively crane's-bill, stork's-bill, and heron's-bill, from the fancied resemblance of the ripe seed-vessel to these objects. Many of the species, which are very widely distributed, are natives of Europe; but the majority of our green-house favourites are from the Cape of Good Hope. The herb Robert (*G. Robertianum*) and the meadow crane's-bill (*G. pratense*) are British plants, as are also *E. cicutarium* and *moschatum*. All the pelargoniums have their flowers in heads, or umbels, and the calyx remains till the seeds are ripe. Their leaves vary very much, some being round—as the horseshoe geranium—and marked with a dark line; and others are deeply lobed, as some of the scented varieties.

The Geraniaceæ are all innocuous plants, being generally slightly acid, and sometimes astringent. They are all more or less fragrant, secreting oils and resins; and in some these secretions are so abundant (*Monsonia spinosa*), that the stems burn like torches, and emit an agreeable odour during combustion. In America, the roots of *G. maculatum* are used as a remedy for diarrhœa; the British Erodiums are sometimes employed as aromatic bitters; from *P. odoratissimum* a fragrant oil has been distilled, resembling the attar of roses; the underground tubercles of *P. hirsutum* are esculent, and prized by the Arabs as food; and Mr Backhouse, in his recent travels, mentions that the tubers of *G. parviflorum* are eaten by the natives of Tasmania, where it is called the Native Carrot. Notwithstanding these uses, the members of the order are chiefly esteemed for the beauty of their flowers, and have long continued among the most admired favourites of the conservatory. The geraniums or pelargoniums which we see at horticultural exhibitions, are chiefly hybrids and improved varieties of the Cape species of *Pelargonium*.

LINACEÆ.—A very small order. The flowers are in five parts, like those of the cloveworts; but the sepals of the calyx are always distinct, and, instead of being arranged in a regular whorl, two are placed a little lower than the others, as in the *Cistaceæ*. There are five styles and stigmas; but the seed-vessel splits into ten valves, each carpel containing two seeds, separated by an obscure partition, which gives the carpels the appearance of being only one-seeded. The seeds are flat and shining, with a large embryo.

The only genera are Linum and Radiola; the former comprehending many species. *L. catharticum* is the purging-flax of rural practice. But of all plants of the order, the common flax (*L. usitatissimum*) is the most important and best known. Flax will grow in almost any part of the world; and though an annual, its stem contains so much woody fibre, that it is exceedingly tough and durable, yielding by maceration the flax of commerce. This external coating of tough fibre, and the peculiar construction of the flower, are amongst the most obvious distinctions of the tribe, though only one or two yield fibre sufficiently strong for economical purposes. The seeds contain a great quantity of oil (*linseed-oil*), which is obtained from them by pressure, and the refuse forms *oil-cake*, employed by farmers in feeding cattle. The seeds also abound in mucilaginous matter, and are thus made use of medicinally, for coughs, &c.; or, when ground into meal, for poultices. Though lint was at one time pretty extensively grown in Britain,

our manufacturers now derive the greater part of their supplies from the countries adjoining the Baltic, from which, in one year, not less than 70,000 tons of flax, and about 2,000,000 bushels of linseed, have been imported. The Valley of the Nile, anciently celebrated for its fine linen, now yields but an inconsiderable quantity, in consequence of the present barbarous condition of the inhabitants. It is there cultivated during the cold season. Of late years, the fibres of flax, by being steeped in a solution of carbonate of soda, and afterwards dipped in a weak acid solution, are so broken up as to form a substance like cotton, which is manufactured in the same way as that fabric.

These and the other orders tabulated in page 89 comprise all the plants belonging to the sub-class THALAMIFLORÆ. They include several interesting members, some of which are of the greatest importance to man. Many of the genera contain only herbaceous plants; and the timber-trees that are among them have all comparatively light wood, though it is generally fine grained, and in some extremely beautiful. Flax and cotton, both belonging to this division, are also of the greatest economical importance. The contrast between the durability of these two kinds of thread is very striking, and of peculiar interest to the student of vegetable physiology. Linen thread, being the *woody fibre* of the flax-plant, is much stronger than cotton thread, which is composed entirely of *cellular tissue*. Though the seeds of many plants are abundantly enveloped in down, that of the cotton is the only one capable of being spun into thread. The Bombax, or silk-cotton-tree, forms no exception to this statement, because though the silky hairs that surround the seeds are used to stuff cushions and beds, and though a sort of felt has been made of them, yet they cannot be spun into threads of sufficient tenacity to endure weaving. Ropes, and other fabrics, are manufactured from the barks of many of the trees and plants included in this division. Cocoa and chocolate, tea, wine, oranges, lemons, maple-sugar, opium, several fruits, drugs, dyes, and oils, are the produce of plants belonging to this division; and to these may be added cabbages, mustard, horse-radish, turnip, and other esculents.

§ CALYCIFLORÆ.

The plants comprised in this sub-class are dichlamydeous—that is, having both calyx and corolla—as in the preceding; the petals are usually separate, but sometimes united; the stamens perigynous, arising from the calyx, and thus surrounding the ovary; or epigynous, arising, apparently, from the upper part of the ovary, which is in this case inferior as regards the parts of the flower. It has been separated into two divisions: the one named *Polypetalæ*, from the petals being several and separated; the other *Monopetalæ*, from their being so united as to appear single; for example, a wild rose has five distinct petals, separate to the base, whereas a bell-flower (Campanula) has all its petals united into one piece. In no case do the stamens arise directly from the thalamus, which is the characteristic of the preceding sub-class. Here the parts of the flower are more or less united to each other. The following are the orders belonging to Calycifloræ:—

POLYPETALÆ.

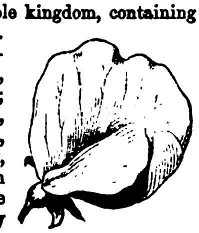
Stackhousiaceæ — Stackhousiads.
*Celastraceæ—Spindle-trees.
*Staphyleaceæ—Bladder-nuts.
*Rhamnaceæ—Buckthorns.
Anacardiaceæ—Cashews.
Amyridaceæ—Myrrh order.
Connaraceæ—Connarads.
*Leguminosæ or Fabaceæ—Leguminous Plants.
Moringaceæ—Moringas.
*Rosaceæ—Rose order.
Calycanthaceæ—Calycanths.
*Lythraceæ—Loosestrifes.
Rhizophoraceæ—Mangroves.
Vochysiaceæ—Vochysia order.
Combretaceæ—Myrobalans.
Melastomaceæ—Melastomads.
Alangiaceæ—Alangiads.
Philadelphaceæ—Syringas.
Myrtaceæ—Myrtles.
Chamælauciaceæ — Fringe-myrtles.
Lecythidaceæ—Monkey-pots.
Barringtoniaceæ — Barringtonias.
*Onagraceæ—Evening Primroses.
*Halorageaceæ—Mare's-tails.
Loasaceæ—Chili-nettles.
*Cucurbitaceæ—Cucurbits.
Papayaceæ—Papaw-worts.
Belvisiaceæ—Belvisiads.
Passifloraceæ — Passion-flowers.
Turneraceæ—Turnera order.
*Portulacaceæ—Purslanes.
Illecebraceæ—Knotworts.
*Crassulaceæ—Stonecrops.
Mesembryanthemaceæ—Fig-marigolds.
Tetragoniaceæ—Tetragonias.
Cactaceæ—Indian figs.
*Grossulariaceæ—Gooseberry order.
Escalloniaceæ—Escalloniads.
*Saxifragaceæ—Saxifrages.
Hydrangeaceæ—Hydrangeads.
Cunoniaceæ—Cunoniads.
Bruniaceæ—Bruniads.
Hamamelidaceæ—Witch-hazels.
*Umbelliferæ or Apiaceæ—Umbel-bearers.
*Araliaceæ—Ivyworts.
*Cornaceæ—Cornels.

MONOPETALÆ.

*Loranthaceæ—Misletoe order.
*Caprifoliaceæ—Honeysuckles.
*Rubiaceæ — Cinchona and Bedstraw order.
*Valerianaceæ—Valerians.
*Dipsaceæ—Teazelworts.
Calyceraceæ—Calycera order.
*Compositæ or Asteraceæ—Composites.
Brunoniaceæ—Brunoniads.
Goodeniaceæ—Goodeniads.
Stylidiaceæ—Styleworts.
*Campanulaceæ—Bell-flowers.
*Lobeliaceæ—Lobeliads.
Styracaceæ—Storax order.
Columelliaceæ — Columellia order.
*Vacciniaceæ—Cranberries.

ANACARDIACEÆ.—This order is chiefly found in tropical America, Africa, and India, in the form of woody plants, with alternate exstipulate leaves, and small, sometimes unsexual flowers. Sepals, 3–5 united; petals, 3–5 imbricate; stamens, variable in number; ovule, solitary, with a long curved cord attached to a basal placenta; the fruit, a nut or drupe, indehiscent. They abound in a resinous or milky acrid, and poisonous juice; but their fruits are often edible, instances of which we find in the cashew-nut (*Anacardium occidentale*), where the kernel is edible, while its covering is acrid. The mango is a highly prized tropical fruit, produced by a plant of this order (*Mangifera indica*), of which there are many varieties in cultivation. The genus *Spondias* affords the eatable fruit called hog-plums, while pistachio-nuts are derived from *Pistacia vera*. On the other hand, several poisonous species have been brought into the service of man: as *Rhus Toxicodendron*, the Poison Oak, which has been used as a remedy in paralysis. The varnish of Martaban is traced to *Melanorrhœa usitatissima;* while Japan lacker is supplied by *Stagmaria verniciflua*, a native of the Indian Archipelago, and mastich by several species of *Pistacia*. The pe-la wax of China, which is now being introduced to European commerce, is furnished by an insect which feeds upon *Rhus succedaneum*.

LEGUMINOSÆ.—This is one of the most extensive and best defined orders in the vegetable kingdom, containing upwards of 6500 known species. Many of its plants bear butterfly-shaped (papilionaceous) flowers, and all have pod-like seed-vessels; among which may be mentioned, as familiar examples, the pea, vetch, bean, lupine, restharrow, broom, furze, and laburnum. In an order so extensive, it may be expected that there will be many minor differences requiring subdivision into tribes; but without adverting to these in the meantime, the following may be stated as the general characteristics of the *Leguminosæ:* —Herbs, shrubs, or trees; leaves, alternate, generally compound, their petioles tumid at the base, where there are usually two stipules, and also two to each leaflet in the pinnate leaves; the pedicels are generally articulated, and the flowers are furnished with small bracts; calyx, five-parted, the segments being sometimes unequal and variously combined; petals, never more than five, but often less, and sometimes wanting, inserted into the base of the calyx, and variously arranged, papilionaceous in all European genera, the odd petal being always



Papilionaceous.

superior; stamens, definite or indefinite, inserted with the petals, in exceptional cases apparently hypogynous, thus shewing a transition from the preceding sub-class, distinct, or in one, two, or three bundles; ovary, superior, for the most part one-celled; ovules, one or many; style and stigma, simple; fruit, a true legume, a modified form of legume or loment, or sometimes, when containing only one seed, drupe-like; embryo, straight, with or without albumen; the radicle, in some instances, bent along the edge of the cotyledons.

This family, says a recent writer, is amongst the most important to man, whether as affording objects of beauty, of utility, or of nutriment. The bean, the pea, the vetch, and the clover tribe belong to it; as do the logwood, the laburnum, indigo, the tamarind, liquorice, senna, and the acacias. Its general properties are considered by some to be wholesome, but there are several exceptions. Thus, the seeds of laburnum, and the juice of *Coronilla varia*, are poisonous. Senna, obtained from various species of cassia, is purgative, and several others of the order possess a similar property. The pericarp of some contains much tannin; dyes are obtained from others; and many yield gums and balsams. It would consume pages to enumerate all the uses to which this, one of the most extensive orders in the vegetable kingdom, has been applied. We shall, therefore, briefly indicate the principal sections of the order, and the more important plants contained in each. § I. *Papilionaceæ*, petals papilionaceous, imbricate, upper one exterior. This, which may be called the Pulse section, is the only one containing British species, but these are numerous, and contribute much to the beauty of our Flora. The vetches and lathyrus of our hedgerows, the restharrow of sandy banks, the trefoils and clovers of our fields, the lotus of our meadows, and the meliloti of ballast hills, are all gay flowers which we gather in our rural walks. Turning to plants of utility, we find here the bean and the pea, so well known as farm and garden crops, the clovers, vetches, saintfoin, lucerne, and other forage plants which form the mainstay of modern farming. The lentil (*Ervum lens*), although a crop of the most ancient cultivation, has only recently been introduced to the notice of British farmers, and may possibly be of some service on light soils. Kidney-beans and scarlet-runners also belong to the list of garden Papilionaceæ, the latter affording a characteristic illustration of the miscellaneous properties of this order, its roots being poisonous, while its seeds form an article of food. Other plants of the section are decidedly poisonous, such as *Coronilla varia*, and the seeds and bark of laburnum, which, being a common ornamental tree, and one which seeds freely, is apt to give rise to accidents, especially in the case of children. But perhaps the most remarkable of all poisonous species is the ordeal bean of Calabar, which was recently described to the Royal Society of Edinburgh by Dr Christison; but its genus is not precisely determined. It appears to be commonly used in Calabar, in trials by ordeal, the suspected party being set free if (by vomiting) the bean does not prove fatal. In like manner, the bark of another species is used by the Caffres as a test in judicial trials. Of miscellaneous plants used in the arts, we find *Astragalus gummifer* and other species, from which gum tragacanth is obtained; *Baptisia tinctoria*, a dye-plant and the wild indigo of America; *Crotalaria juncea*, whose fibrous bark yields Bengal hemp; *Dalbergia Sissoo*, which in India yields the valuable timber well known by its native name of Sissoo; *Dipterix odorata*, whose fragrant seeds are the Tonka-beans of commerce; *Glycyrrhiza glabra*, whose root forms liquorice; various species of *Indigofera*, from which the true indigo is obtained; *Pterocarpus santalinus*, the source of red sandal-wood; *P. draco*, which yields gum dragon; and *Triptolomea*, from species of which the rose-wood of commerce appears to be derived. Kino is supplied by various species of *Pterocarpus*, and by *Butea frondosa*, one of the most gorgeous plants of India, whose masses of bright orange-red flowers, with jet-black velvety calyces, are described by Dr Hooker as resembling sheets of flame. § II. *Cæsalpinieæ*, petals imbricated, upper one interior. The plants of this section are chiefly important from yielding valuable timbers and dyes, while some are much used as purgative medicines. Of the latter, the various kinds of senna, consisting of the leaves of species of *Cassia*, are most important. The fruit of the tamarind likewise contains a laxative pulp, as also *Cassia Fistula*. Of dyes we have the sappan of India (*Cæsalpinia sappan*), the barwood or camwood (*Baphia nitida*), and the well-known logwood (*Hæmatoxylon campechianum*). Of timber-trees, the Brazil-wood of commerce (*Cæsalpinia Brasiliensis*) is not the least important. The West Indian locust-tree (*Hymenæa Courbaril*) affords a close-grained tough wood, which is found well adapted for the beams of steam-engines, while the Guiana purple-heart even excels it in toughness; and being found to resist well the shock of artillery discharges, it is sought after for mortar-beds. Lindley speaks of the locust-trees of the West as long celebrated for their gigantic structure, while other species are the colossi of South American forests. Martius represents some as eighty-four feet in circumference at the base of the stem; by counting their concentric rings, he arrived at the conclusion that they were of the age of Homer, and 332 years old in the days of Pythagoras. One estimate reduced their antiquity to 2052 years, but another carried it up to 4104; from all which he argues that the trees cannot but date far beyond the time of our Saviour. § III. *Mimoseæ*, petals valvate in estivation. The principal genera are *Acacia* and *Mimosa;* the latter genus chiefly remarkable on account of the irritability displayed by the leaves of *M. pudica* and *sensitiva*. Many species of *Acacia* yield gum-arabic and gum-senegal. The Australian species, called 'Wattles,' have astringent bark which is used in tanning; in these the leaf-stalk is often flattened into a phyllodium, or false-leaf; in the young plant there may be no compound leaves developed, but these ultimately appear at the tips of the phyllodia.

ROSACEÆ.—Like the preceding, this is one of the most extensive natural orders, comprehending nearly 1000 described species, which are herbs, shrubs, and trees, often of very dissimilar habits and appearance, but all bearing a striking resemblance in their fructification to the single or wild rose of our woods and hedges, which may be taken as the type of the order. Among the trees may be mentioned, as familiar examples, the almond (*Amygdalus*), the pear and apple (*Pyrus*), the sloe and plum (*Prunus*), the peach and nectarine (*Persica*), the cherries and laurels (*Cerasus*); among the shrubs, the rose (*Rosa*), the hawthorn (*Cratægus*), the bramble and raspberry (*Rubus*), and the quince (*Cydonia*); among the herbs, the common yellow *Potentilla* of the roadsides, the *Geum*, the *Tormentilla* of our woods and commons, and the delicious strawberry (*Fragaria*). From the mention of these plants, the reader will be enabled to form some idea of the order, and to perceive that the varied nature of its genera requires a subdivision into several tribes for the purposes of detailed description. All the different sections into which the *Rosaceæ* have been arranged, exhibit the following general characteristics:—Leaves, alternate, generally compound, and always furnished with stipules; calyx, five-lobed, united below, but separate and expanding above; corolla, of five, or sometimes four petals. The ovary is one-celled, and there is seldom more than one seed, scarcely ever more than two in each cell. Carpels numerous, and generally enclosed in the fleshy tube of the calyx.

Rosaceous Flower.

Rosaceæ is usually divided into the following tribes:—1. CHRYSOBALANEÆ, or cocoa-plum family, represented by *C. icaco*, an irregular shrub, eight or ten feet high, found in South America and the West Indies, where its fruit, which is about the size of a plum, of a whitish-yellow, and possessing a sweetish taste, is brought to the markets. There are about nine genera belonging to this tribe, all of which are trees or shrubs, with simple alternate stipulate leaves, and flowers in racemes or panicles. They are natives of the warmer parts of Africa and America, and differ from the almond tribe in having irregular petals and stamens, and in the style arising from the base of the ovary; the stipules are not united to the petiole. 2. AMYGDALEÆ, or almond family, represented by the common almond (*Amygdalus communis*), and embracing the peach, apricot, nectarine, plum, cherry, &c., well known for their delicious fruits, and a few bushes remarkable for their gay appearance during the flowering season. The fruits of this tribe are for the most part edible; and though the leaves and bark possess medicinal properties, yet one of the most subtile poisons—prussic acid—can be extracted both from the fruit and leaves of the almond. 3. SPIRÆEÆ, deciduous shrubs and perennial herbs, represented by *Spiræa salicifolia*, or brideswort. In this section the five-cleft calyx is lined with the dilated receptacle, which forms a sort of cup for the carpels, which are in the form of follicles. The beautiful hardy shrub named *Neillia thyrsiflora* belongs to this tribe, which contains a large number of shrubby ornamental *Spiræas*, as well as herbaceous kinds. 4. DRYADEÆ, embracing those plants which agree with the common *Potentilla* in the construction of their flowers—that is, in having a calyx of ten sepals; its tube short, or nearly flat, not enclosing the fruit; a corolla of five petals; and the stamens, which are numerous, forming a ring round an elevated or flat receptacle, on which are placed numerous carpels. By this test the student will find that the section comprises not only herbs, such as the potentilla, geum, tormentilla, and strawberry, &c., but also erect and trailing shrubs, as the raspberry and bramble. These genera, though alike in their flowers and in many of their habits, are otherwise very dissimilar. In the potentilla, for example, the carpels form the prominent part of the so-called fruit, while in the strawberry the receptacle dilates and becomes edible. Again, in the raspberry the receptacle is a torus surrounded by the carpels, which swell out and soften, forming the edible portion. The leaves and stems of these genera are also very dissimilar, but the habit of increasing by suckers or runners is very prevalent in all. 5. SANGUISORBEÆ, a section of herbaceous perennials, illustrated by *Sanguisorba officinalis*, or the weed burnet of our pastures. This tribe is distinguished by having one or two achenes enclosed within the dry calyx-tube. The flowers often have no petals, but the clefts of the calyx are coloured instead, and the flowers are generally furnished with glossy coloured bracts. 6. ROSEÆ, or roses proper, the type of which is the single wild-rose, or dog-rose of the hedges. The general characters of this section are too well known to require much description. It is distinguished botanically by the numerous achenes enclosed in a fleshy calycine tube which is contracted at the orifice. They have all a corolla of five equal slightly indented petals, capable of being increased indefinitely by cultivation; numerous stamens; a five-cleft calyx. The pitcher-shaped portion of the calyx becomes the hip as the seeds ripen, and forms a false pericarp, enclosing the numerous bony carpels. Many of the plants have pinnate leaves and prickly stems—the prickles differing from thorns in being articulated to the stem—that is, of being separable without tearing the bark. Most of them are fragrant, and the leaves of some, as the sweetbrier, are replete with a fragrant volatile oil, which appears to be secreted by beautiful glands dispersed all over the foliaceous surface of the plant. 7. POMEÆ, an extensive and varied section, the type of which is the common apple (*Pyrus malus*). It comprehends the apple, pear (*Pyrus communis*), the mountain-ash (*P. aucuparia*), the wild service (*P. torminalis*), the quince (*Cydonia*), and the hawthorn (*Cratægus*). In all of these genera, which are trees and shrubs, the flowers are remarkably similar; but the habits of the plants, the leaves, and the fruit, present numerous differences.

The properties of the order have already been so far noticed in the preceding detail, that it may be stated of them generally as follows:—The fruit of some of the *Chrysobalaneæ* is eaten under the name of the cocoa-plum. The *Amygdaleæ*, including the almond, plum, cherry, sloe, &c., are well known; the leaves and kernels contain prussic acid, which, in a concentrated form, is one of the subtilest poisons; but being generally diluted in a natural state with gum, sugar, &c., it is harmless, and serves to give an agreeable flavour to the fruits containing it. Of the *Potentilleæ*, the roots of several are astringent and febrifugal, and the fruits of such as the raspberry and strawberry are delicious and wholesome. The *Roseæ* are chiefly valued for their ornamental flowers, but they also yield valuable extracts—as attar of roses, rose-water, conserve of roses, &c. The fragrant essential oil called attar of roses is distilled chiefly from the common cabbage-rose (*Rosa centifolia*) and its varieties; 20,000 flowers of roses are required to make a rupee weight of the attar, which sells for £10. The common dog-rose of our hedgerows yields an astringent fruit employed in diarrhœa, and is used by gardeners as a stock on which to bud the fine kinds of exotic roses. The *Pomeæ*, under cultivation, supply wholesome and delicious fruits, of which the apple, pear, quince, and service-berry are familiar examples.

MYRTACEÆ.—This important order consists of upwards of 60 genera, and about 1300 species. They are all trees or shrubs, often with angled branches, with simple exstipulate leaves, which are for the most part opposite, full of transparent dots, and with an intra-marginal vein round the edge. The substance of the leaf is coriaceous, and the dots are glands, or cysts, full of a fragrant volatile oil. The inflorescence is both terminal and axillary, variable in its form, but generally aggregate—the flowers being regular and united, of a white, red, or sometimes yellow colour, but never blue. The tube of the calyx adheres to the ovary, and is from four to eight cleft, persistent or deciduous. The petals, which are rarely wanting, are equal in number to, and alternate with, the segments of the calyx; the stamens are inserted with the petals, and are twice as many, or (usually) indefinite, and then arranged in several series;

Pomegranate.

the anthers are oval, two-celled, and burst longitudinally. Fruit, baccate or capsular; style and stigma, simple; many-celled, or one-celled by the obliteration of the

dissepiments of the carpels. Seeds, generally indefinite, seldom few, and without albumen.

The myrtle-blooms are possessed of many useful as well as ornamental properties. Among the edible fruits may be mentioned the delicious guava, yielded by several species of *Psidium;* the rose-apple and jamrosade, produced by *Eugenia* and *Jambosa.* Of spices yielded by the order, which are all more or less aromatic, we have the clove, which is the unexpanded flower-bud of the *Caryophyllus aromaticus;* all-spice, Pimento or Jamaica pepper, the dried berries of *Eugenia pimento;* and also the dried berries of the common myrtle. It is the volatile oil found in the dots of the leaves, the unexpanded petals, and in almost all the parts of the plant, that gives to them their fine aromatic fragrance. The pomegranate (*Punica granatum*) forms a delicious fruit in warm countries; the pericarp or rind is used in the East as an astringent; and the bark of the root is esteemed an efficient anthelmintic.

Some species of the beautiful genus *Metrosideros* yield hard and heavy timber, which the South Sea islanders prize for their clubs and other weapons of war. The gum-trees of Australia deserve special notice as among the most valuable economical plants of our Australian colonies. They are distinguished by a remarkable operculate calyx, and their bark separates in layers, giving rise to the statement that the trees of Australia shed their bark instead of their leaves in winter. Their leaves often stand in a vertical position, and are remarkably hard and coriaceous. These trees grow to an enormous size, and yield very durable timber, where it is capable of being worked. They supply the place of the European oaks as a source of tannin. *E. resinifera* yields, on incision, an astringent matter, called Botany Bay kino; while several others yield saccharine matter. A peculiar red gum is contained in cavities of the wood of *E. robusta.*

LECYTHIDACEÆ.—This order is remarkable from the usually circumscissile dehiscence of its fruits, which form the monkey-pots so common in museums of vegetable products.

CUCURBITACEÆ.—This is a large and interesting family of herbaceous plants, containing 56 known genera, and about 300 species. The roots are annual or perennial, fibrous or tuberous; the stems succulent, climbing by means of lateral tendrils formed of the abortive stipules, and furnished with large alternate, palmated rough leaves. The flowers are usually unisexual.

The Cucurbits are natives of all hot climates, but are most abundant in India; a few exist in the northern parts of Europe and America, and some are found at the Cape of Good Hope.

In an economical point of view, the order is of considerable importance, furnishing the well-known esculents—the cucumber, melon, gourd, pumpkin, and calabash; and the purgatives colocynth and elaterium. The general properties of the gourd family may be regarded as bitter and purgative—these qualities pervading more or less all the species, and rendering their fruit either esculent or purgative. The seeds of all are sweet and oily, and from some a considerable quantity of fine-flavoured oil may be expressed. The roots and leaves are sometimes replete with a bitter drastic juice. The fruit of many of the members grows to an enormous size; the calabash, for example, being sometimes found six feet long and eighteen inches in circumference. *Gherkins* are the fruit of the common cucumber, pickled when in a young state. The fruit of *Lagenaria vulgaris* is in common use for water-bottles in the Greek islands and generally in the East. It has probably given rise to the clay water-bottles in form of a round bulb ending in a long neck, which much resemble it in shape, and to which the bottles in use all over the world may be traced as modifications. Many of the ornaments of ancient Egyptian architecture are traceable in a similar manner to vegetable forms peculiar to the region.

CACTACEÆ.—The Indian figs, or Cacti, constitute one of the most singular and interesting orders in the vegetable kingdom. They are unique in their forms and habits, having perennial succulent, angular, or rounded spiny stems. In general, the stems and branches are jointed; the leaves are either very minute, or altogether wanting, their place being supplied by strong spines. They are all natives of tropical America, but thrive well in all hot, dry, and exposed places. Of the more common genera, we may mention the following:—*Mammillaria*, so called from the pap-like tubercles which cover its sub-cylindrical stem. Each tubercle is crowned with a little tuft of radiating spines; and the flowers, which are sessile, are ranged in a kind of zone round the plant. The melon cactus (*Melocactus communis*), which has a more or less globose stem, with alternate furrows and ridges, the latter being armed with tufts of spines; the stem is crowned by a woolly tuft, from which spring the flowers. The hedgehog-thistle (*Echinocactus*) has also a globose stem, but wants the woolly head, and has its flowers springing from the tufts of spines which arm the ridges. The torch-thistle (*Cereus*) has the stem angular, the projecting angles being armed with spiny tufts, from which the flowers generally spring. The old-man cactus (*Pilocereus senilis*) is so called from its resemblance to an old man's head, being covered with long white hairs. In our hothouses, it is generally of small size; but in its native country it is said to attain the height of twelve or fifteen feet. The Peruvian torch-thistles (*C. peruvianus* and *hexagonus*) are still more gigantic plants, often attaining a height of forty feet, though their stems be not thicker than a man's arm. The rat's tail cereus (*C. flagelliformis*) is well known from its long whip-like stems, which hang down from the sides of the suspended pots in which it is usually grown. The night-flowering cereus (*C. grandiflorus*), so called from its blossoms opening during night, and fading before morning, has an angular, branched, and climbing stem, throwing out roots at every point. The flower is of large size and magnificent, the rays of the calyx being of a bright yellow when open, and the petals of the most delicate white. The genus *Rhipsalis* has slender-jointed stems, which look like samphire; and the opuntias, which are numerous and useful, are distinguished by their round, flat, leaf-like bodies, united together by joints, and for the most part covered with spines.

The fruit of many of the Cactaceæ is esculent, but is rather insipid, having little of that acidulous flavour which characterises the Currantworts, to which the family is allied. It is upon the *Opuntia cocchinellifera*, the Nopal plant, that the cochineal insect, so valuable in the arts, chiefly feeds. It is stated that not less than 800,000 pounds of cochineal are annually brought to Europe, one-fourth of which is consumed in Britain alone, at the cost of £300,000 sterling; so valuable to man is an insect which ignorance would be apt to regard as mean and insignificant. In the south of Europe, the prickly pear (*O. communis*) is reared as a hedge, and also for its fruit, which is edible, and yields a rich carmine pigment; and the Indian fig (*O. tuna*) is grown for similar purposes in Brasil. In our conservatories, the cactuses are cultivated as ornamental plants alone, either for the beauty of their flowers or the singularity of their forms.

GROSSULARIACEÆ.—This is a well-known order, consisting principally of one genus, *Ribes*, which includes all the gooseberries and currants of our gardens. The species, of which there are upwards of eighty, are unarmed or thorny shrubs, with round or irregularly angled stems and branches; simple, lobed, alternate leaves, destitute of stipules and tendrils. The inflorescence is axillary and in racemes. The calyx, which is often coloured, is four or five cleft; petals, perigynous, equal in number to, and alternate with, the segments of the calyx; stamens, of the same number, alternate, and

inserted with the petals; filaments, distinct; anthers, two-celled, bursting longitudinally; ovary, one-celled, cohering with the tube of the calyx; ovules, indefinite; fruit, a berry, crowned with the remains of the flower, one-celled, filled with pulp with two parietal placentas; seeds, numerous, suspended among the pulp by filiform funicles; testa, externally gelatinous; albumen, horny.

The order is very conveniently grouped into two sections—namely, the Gooseberries, which have prickly stems, and the flowers either singly, or in clusters of not more than two or three; and the Currants, which are entirely without spines, and the flowers in racemes. There are a few species, such as *Ribes dracantha* and *saxatile*, which may be considered as intermediate, these having the spines and habit of growth of the one, and the racemose inflorescence of the other. The common gooseberry (*R. Grossularia*), the red currant (*R. rubrum*), the black currant (*R. nigrum*), and the flowering currant (*R. sanguineum*), are familiar examples of the order, and all too well known to require any detailed description. The gooseberry is found wild in many parts of Britain; and is reared in the north of England to greater perfection than in any other country, Lancashire prize-specimens having been known to weigh an ounce and a half.

Gooseberries and currants are well known as agreeable acid fruits, their acidity or sweetness depending upon the relative quantities of malic acid and sugar which they contain. They are used both as dessert and kitchen fruits; preserved with sugar, they make the best jams and jellies; and when fermented, produce wines little inferior to that of the grape. The blackberry has tonic and astringent properties, infusions of the leaves being used for this purpose. (See THE FRUIT GARDEN.)

SAXIFRAGACEÆ.—This order consists chiefly of very small herbaceous plants, with alternate or opposite leaves, and is readily distinguished by the peculiar ovary, which is more or less completely inferior, consisting of two carpels which diverge at the apex. As useful plants, they are unimportant, but they are the most charming that greet the eye of the botanist in his mountain rambles. *Saxifraga stellaris* and *S. aizoides* are the great ornaments of Highland streams at a low elevation; while higher up, the rocky banks are covered with a purple carpet of *S. oppositifolia*, or the rarer *S. rivularis*, which attracts many a botanist to the summit of Loch-na-gar. But it is not alone the Scottish mountains that are adorned with these 'alpine gems;' *S. Boussingaultii* reaches to nearly 16,000 feet on Chimborazo.

UMBELLIFERÆ.—This is one of the most extensive and important of the natural orders, comprising about

Hemlock.

300 genera, and above 1500 species. The genera, though presenting many minor differences, are, on the whole, well marked; so that no one who has seen the flower of the parsley and common hemlock can have any difficulty in detecting an umbelliferous plant. The species are for the most part herbs, seldom shrubs, with fistular furrowed stems, loving damp waste places, and varying much in their properties, according to the climate under which they are grown. The leaves are generally divided, sometimes simple; are alternate, and clasp the stem by a broad sheathing petiole. The flowers are white, pink, yellow, and blue, and in umbels, which are simple or compound, and these are with or without bracts at their base: when seated at the base of the umbel, the bract is called an involucre; when at the base of the umbellules in the compound head, an involucel. The calyx is superior and five toothed; petals, five, and inserted on the outside of a fleshy disc, which is placed on the top of the ovary; stamens, five, and inserted alternately with the petals; ovary, inferior, and two-celled, with pendulous ovules; styles, two, distinct; stigmas, simple. The fruit consists of two carpels, united by a common axis, from which they separate when ripe; the external part of the carpels is traversed by linear ridges, which are divided into primary and secondary, there being five of the latter, and four of the former, between them. The ridges are separated by channels, below which are often placed, in the covering of the seed, receptacles or vittæ of an oily matter. The seed is pendulous, usually cohering with the carpel, rarely loose.

Among the more familiar genera may be mentioned the parsnip (*Pastinaca*), the cow-parsnip (*Heracleum*), the celery (*Apium*), the carrot (*Daucus*), the hemlock (*Conium*), the cow-bane (*Cicuta*), and the coriander (*Coriandrum*). Several relations have been pointed out between the Umbelliferæ and other orders; such as their agreement with the Crowfoots in the sheathing leaves, the acrid juice, and large albumen; with some of the Geraniums in their habit, form of leaves, and poisonous properties; and with Ivyworts, from which they differ little, except in the parts of the flower.

The properties of this order are very variable and important. Generally speaking, all the genera are characterised by an acrid principle, which is well developed in the hemlock, rendering the roots of that plant virulently poisonous. This principle is more or less disposed throughout the whole order, but is often enfeebled by change of situation, or altogether destroyed by cultivation. Thus the wild plants from which garden celery and other esculents are derived, are poisonous. In like manner, Dr Christison has found a reputedly poisonous species of *Œnanthe* to be innocuous when grown in the neighbourhood of Edinburgh. Another important secretion is the aromatic oil contained in the vittæ of the pericarp, which is used in diet as a condiment, and in medicine as an aromatic and carminative. It is found abundantly in the anise, caraway, dill, cumin, and coriander. A gum-resinous exudation characterises others of the genera, which yield the valuable medicines asafetida, galbanum, opoponax, &c. The roots of many of the Umbelliferæ, when cultivated and properly treated, are replete with starch and sugar—as, for example, the common carrot, the parsnip, the skirret, and the arracacha of the South Americans.

LORANTHACEÆ.—These are parasitical plants, with stems and branches in articulations, which often fall to pieces in drying. They are chiefly natives of the equinoctial regions of Asia and America, but a few are European and African, and we have one British representative of the order in *Viscum album*, the 'misletoe bough' of Christmas times, which was held sacred by the Druids.

CAPRIFOLIACEÆ.—A well-known order, consisting of 12 or 14 genera, and about 220 species. They are erect or twining shrubs, rarely trees, having opposite, simple, or pinnate leaves, without stipules; and flowers terminal in corymbs, or axillary. The flowers are white,

scarlet, or yellow, and often sweet scented, as in the common honeysuckle.

The order has been divided into two sections—namely, the SAMBUCEÆ, or elder tribe, and the LONICERÆ, or true honeysuckle tribe. In the former, the corolla is regular and rotate, seldom tubular; ovary, three or four celled; style, none; stigmas, three, sessile; raphe on the inner side of the ovule. It includes the genera *Sambucus* and *Viburnum*. In the latter, the corolla is tubular, often irregular; style, one; berry, from two to four celled, each cell containing one or many seeds; raphe, on the outer side of the ovule. It embraces the genera *Caprifolium*, *Lonicera*, *Triosteum*, *Diervilla*, *Abelia*, *Symphoricarpus*, *Linnæa*, &c. As examples of the first tribe, may be mentioned the common elder (*Sambucus nigra*)—well known by its pinnate leaves and terminal cymes of white flowers, which appear in June; by its dark purple pulpy berries, which ripen in September; and by its yellow wood, with a light white pith; also the dwarf elder or danewort (*S. Ebulus*). The laurustin (*Viburnum Tinus*) is a well-known evergreen, whose showy white flowers appear during winter; and the Gueldres rose (*V. Opulus*) is common in gardens under the name of the 'snowball-tree.' In the Viburnums the leaves are not pinnate, and the wood is hard, and without the spongy pith of the elders. As examples of the second tribe, may be mentioned, the honeysuckles (*Lonicera*), the snow-berry (*Symphoricarpus*), and the graceful *Linnæa borealis*, named in honour of the immortal botanist. The Caprifoils grow chiefly in the temperate regions of the northern hemisphere, and delight in cool shady places.

The properties of the order are varied, and of considerable utility. The berries of the elder are fragrant and sudorific; they contain malic acid, and a wine is often made from them. The leaves are emetic and purgative; and the berries, in a green state, are poisonous to some animals. The wood, which is hard and yellow, is used by turners. The wood of the wayfaring-tree is said to be in great repute for the tubes of tobacco-pipes in some parts of Turkey; and the bark yields a viscous substance, used as birdlime. The roots of *Triosteum* and *Diervilla* are used in America instead of ipecacuanha; and the berries of *T. perfoliatum* are said to form no bad substitute for coffee. The honeysuckle is a purgative, but is cultivated principally as a handsome and fragrant climber. Indeed, the whole are grown more for their beauty than economical uses—the climbing species for adorning old walls and trunks of trees, and the upright sorts for their shelter and ornament in pleasure-grounds.

RUBIACEÆ.—This is a large, and in many respects not a well-defined order, composed of small trees, shrubs, and herbs. It has been proposed to separate it into two orders—CINCHONACEÆ, containing those plants most resembling cinchona; and GALIACEÆ, those most resembling the galiums or bedstraws. The *Cinchonaceæ* and *Galiaceæ* indeed form two well-marked groups of plants, abundantly distinct from each other in habit and in geographical distribution: the one consisting of trees, shrubs, and herbs, with opposite or verticillate leaves and interpetiolar stipules; almost exclusively inhabiting the hotter parts of the world, most of them eminently conspicuous for their economical products and the beauty of their broad foliage and flowers, although some of them are mean weeds; the other composed entirely of straggling herbaceous plants, with weak angular stems and narrow verticillate exstipulate leaves, inhabiting northern countries, and, with one or two exceptions, alike inconspicuous for use and ornament. Unfortunately, however, fructification does not supply any character whereby those two ideally distinct groups of plants can be clearly separated from each other, and in the limitation of natural orders something more than a difference of habit is considered requisite. The recent discovery of the peculiar axillary glands of *Cinchonaceæ* in *Galiaceæ* serves still further to break up the supposed distinctions between these groups. Decandolle has proposed a further subdivision into thirteen sub-tribes.

By far the greater number of the species are tropical plants, though many are amongst the most common and neglected of British weeds. Madder (*Rubia tinctorum*) is common in gardens, and is much cultivated in Belgium and Holland for its roots, which yield a rich brownish-red dye. The *Galiums* or bedstraws are familiar plants, growing on hedges, on dry banks, or sides of old ditches, and known by the common name of cleavers, ladies' bedstraw, crosswort, and the like. *Asperula odorata*, another of the order, is the well-known woodruff, which acquires, when dried, a most delicate fragrance. The coffee-tree (*Coffea*), Jesuit's bark (*Cinchona*), the Cape jasmine (*Gardenia*), and ipecacuanha (*Cephäelis*), are also well-known members.

The properties of the order are very varied. The roots of many, as the madders and bedstraws, contain a large quantity of colouring-matter; and it is said that fowls fed upon the roots of some plants of this order have their bones dyed of a red colour; in other cases, the plants are acrid, emetic, purgative, or diuretic. The bark (as that of the Cinchona, or Peruvian bark) is sometimes bitter, tonic, and astringent, and highly prized in intermittent fevers. Exertions have recently been made by Dr Anderson to introduce the cultivation of Cinchona to India, where the climate is highly suitable for the production of this important drug. The value of the roasted albumen of the coffee-berry is too well known to require allusion; and the fruits of others of the order have been recommended as answering the same purpose. Among our ancestors, the dried soft haulm of the galiums was much used for beds; hence the term 'bedstraws.'

COMPOSITÆ.—This is one of the most extensive of the natural orders, containing not fewer than 900 genera, and between 9000 and 10,000 species. The members are herbaceous plants or shrubs, with leaves alternate or opposite, without stipules, and usually simple. What is called the flower is an aggregation of unisexual or hermaphrodite *florets*, collected in dense heads upon a common receptacle, surrounded by an involucre, as exemplified in the common daisy, marigold, and dandelion. As the compound leaf is composed of a number of leaflets, so is the composite flower made up of a number of florets arranged on one receptacle, which is furnished with a calyx-like involucre. Each floret is complete in itself, having all the appendages of bracts, calyx, corolla, stamens, and pistil, although the calyx is in a much reduced state, appearing in the form of bristly hairs. The corolla is monopetalous, and either ligulate, tubular, or bilabiate—that is, has two equal lips cut into several lobes. The stamens are equal in number to the teeth of the corolla, and alternate with them; the anthers grow together, so as to form a kind of cylinder, through which passes the style, ending in a two-lobed stigma. The ovary is inferior, one-celled, with a single erect ovule. The fruit is an achene, which retains the pappus when ripe, and falls without opening; the appearance of this pappus or down is familiarly illustrated in the head of the ripe dandelion.

The Composite order has been divided into three sections:—1. *Cichoraceæ*, in which all the florets are ligulate and perfect. 2. *Corymbiferæ*, most of the florets tubular, all hermaphrodite, or those of the circumference filiform or tubular, and pistiliferous or ligulate; style, not jointed. 3. *Cynarocephalæ*, all the florets tubular; style, jointed. The Composite plants are widely scattered over the globe, forming, according to some authorities, one-twelfth of its vegetable productions. Humboldt states that they constitute one-seventh of the flowering-plants of France, one-eighth of those of Germany, one-fifteenth of those of Lapland, a sixteenth of those of New Holland, a sixth of the North American Flora, and one-half of that of America within the

tropics. Though their increase and decrease do not follow any law of climate, it may be stated generally that the Cichoraceæ are chiefly found in cold, and the Corymbiferæ in warm regions. The Composites are herbaceous in the colder quarters of the globe, and become shrubby as we approach the equator.

The Cichoraceæ are well illustrated by the common lettuce (*Lactuca*), the dandelion (*Taraxacum*), the succory (*Cichorium*), and the sow-thistle (*Sonchus*), which are common and familiar British plants. All the members of this section yield a milky juice, which is bitter, astringent, and slightly narcotic. Many of them are used in medicine—as the lettuce, from which the narcotic and diuretic *Lactucarium* is obtained. Many are also used as articles of food; thus, endive (*C. Endivia*) is employed as a salad; so is the garden lettuce when young, the root of the sonchus, and perhaps, more than all, the root of *C. Intybus*, or wild succory, which is roasted and largely mingled with coffee under the name of chicory. The Corymbiferæ, which have the central florets tubular, and the outer ones generally ligulate, are illustrated by the daisy

Chamomile.

(*Bellis perennis*), the chamomile (*Anthemis nobilis*), the groundsel (*Senecio*), the tansy (*Tanacetum vulgare*), the dahlia, marigold, &c. The juice of this section is watery; sometimes bitter and tonic, and sometimes acrid. Many of them contain volatile oils, which are used for various purposes, and some yield yellow and other dyes. Among the most useful of the section may be mentioned the Jerusalem artichoke, wormwood, chamomile, tansy, and arnica—the last much employed in homœopathic practice; indeed, most of the Corymbiferæ are of medicinal value. *Cynarocephalæ.*—The plants of this division are bitter and tonic. By cultivation, this bitterness is lessened, and they become edible. The section may be illustrated by the cardoon and common artichoke, all the thistles (*Carduus*), the burdock (*Arctium*), the corn bluebottles (*Centaurea*), the safflower (*Carthamus*). The properties of the artichoke are well known, as are also those of the carthamus, which is used in dyeing as well as in medicine. The thistle is chiefly interesting as being emblematical of Scotland; but neither antiquaries nor botanists have been able to discover with certainty the species entitled to the appellation of *the* Scotch thistle. *Onopordum Acanthium* adorns the grave of Burns in Dumfries, and is usually employed in national demonstrations; but Burns had another species in view as the 'bur-thistle'—namely, *Carduus lanceolatus*. Others prefer the milk-thistle; and so far as the figures on the coins of the Scotch kings indicate a special species, the milk-thistle appears to be the one.

VACCINIACEÆ.—This order contains two well-known genera—*Vaccinium*, the bilberries and whortle-berries; and *Oxycoccus*, the cranberries. They are humble shrubs, with alternate, leathery leaves, a close-growing bushy habit, and round or angled stems. The flowers are solitary, or in racemes, and in their general structure differ little from the heaths, except in the ovary being inferior. In Vaccinium, the stamens are eight or ten, and the anthers horned or spurred; in Oxycoccus, the stamens are eight, and the anthers without spurs. The members are natives of Europe and America; the former genus delighting in high dry situations, and the latter in marshes and swamps. Both yield edible berries, which have austere antiscorbutic properties. The bilberry or blaeberry (*V. Myrtillus*) of our woods and hills is familiar to every one, as also the whortleberry (*V. Vitis-Idæa*). In North America there are many species—as, *V. angustifolium* (bluets); *V. stamineum* (deer-berries); and *V. frondosum* (blue tangles). Of the cranberry there are two species—*O. palustris*, the common cranberry of European morasses; and *O. macrocarpa*, the American cranberry, which has a larger and more oblong fruit. The berry of both is extensively collected, and used for tarts and other conserves.

§ COROLLIFLORÆ.

In this section the flowers are dichlamydeous, the petals united into a tube, hypogynous, stamens inserted in the corolla (or in the first four orders arising directly from the receptacle). The plants may usually be recognised by the corolla appearing to consist of one piece, the petals being united (gamopetalous). Many of the orders have regular flowers, but a large number have them two-lipped, and therefore irregular, such as the Foxglove, labiate plants, and Acanthi.

The following are the orders contained in this section:—

*Ericaceæ—Heathworts.
*Pyrolaceæ—Winter-greens.
*Montropaceæ—Fir-rapes.
Epacridaceæ—Epacrids.
Ebenaceæ—Ebenads.
*Aquifoliaceæ—Holly order.
Sapotaceæ—Sapotads.
Myrsinaceæ—Ardisiads.
Jasminaceæ—Jasmines.
*Oleaceæ—Olives.
Salvadoraceæ—Salvadora order.
Asclepiadaceæ—Asclepiads.
*Apocynaceæ—Dogbanes.
Loganiaceæ—Strychnads.
*Gentianaceæ—Gentianworts.
Bignoniaceæ—Trumpet-flowers.
Gesneraceæ—Gesnerads.
Crescentiaceæ—Calabash-trees.
Pedaliaceæ—Pedalium order.
*Polemoniaceæ—Phlox order.
Hydrophyllaceæ—Water-leaves.
Diapensiaceæ—Diapensia order.
*Convolvulaceæ—Bindweeds.
*Cuscutaceæ—Dodders.
Cordiaceæ—Sebestens.
*Boraginaceæ—Borageworts.
Ehretiaceæ—Ehretia order.
Nolanaceæ—Nolana order.
*Solanaceæ—Potato order.
*Atropaceæ—Nightshades.
*Orobanchaceæ—Broom-rapes.
*Scrophulariaceæ—Figworts.
*Labiatæ or Lamiaceæ—Dead-nettles.
*Verbenaceæ—Verbenas.
Stilbaceæ—Stilbids.
Selaginaceæ or Globulariaceæ—Selagids.
Acanthaceæ—Acanthads.
*Lentibulariaceæ—Butterworts.
*Primulaceæ—Primulas.
*Plumbaginaceæ—Leadworts.
*Plantaginaceæ—Ribworts.

ERICACEÆ.—This is an extensive order of shrubs or under-shrubs, with leaves evergreen, rigid, entire, whorled, or opposite, and without stipules. 'The name of the heath family,' as it has been very appropriately remarked, 'conjures up immediately the image of a number of narrow-leaved plants, with globular, ventricose, or bell-shaped flowers; and we are apt at first to think that the family is so natural a one as to require very little explanation.' Did the order include only the heaths, this would be the case; for all the heaths, differing as they do in some particulars, may be recognised at a glance; but as the order includes the Rhododendrons, the Azaleas, and Kalmias, besides several other plants which have not so strong a family likeness to each other as the heaths, it becomes necessary to say a few words on the botanical resemblances which connect them together. The first and most striking of these is the shape of the anthers—each of which appears like two anthers stuck together—and the manner of their opening, which is always by a pore or round hole in the upper extremity of each cell. The filaments also in all the genera grow from beneath the seed-vessel, being

generally slightly attached to the base of the corolla. There is always a single style with an undivided stigma, though the capsule has generally four cells, each containing several small seeds. The calyx is four or five cleft, and the corolla is tubular, with a larger or smaller limb, which is also four or five cleft. The above are the connecting points between the various genera which compose the family; but the differences are such as, according to most botanists, to require a subdivision of the Ericaceæ into four sub-orders, or even into four distinct and independent orders. Adopting the former idea, we shall consider the heath family under the following subdivisions:—1. *Ericeæ*, or those most closely resembling the true heaths, their fruit being loculicidal, rarely septicidal or berried, and the buds naked; 2. *Rhododendreæ*, those allied to the Rhododendrons, their fruits being capsular septicidal; the buds, scaly, resembling cones; 3. *Pyroleæ*, those allied to the winter-green of our woods, and distinguished by having a minute embryo at the base of fleshy albumen, the two preceding having a cylindrical embryo in the axis of the albumen. 1. *Ericeæ.*—This sub-order may be arranged into two sections—namely, the true heaths (*Ericidæ*), having bracteal pedicels of flowers, the corolla of each flower being more or less bell-shaped or globose, with a four-cleft limb, a four-lobed calyx, and eight stamens; and the *Andromedidæ*, which have the corolla more globose, the limb five-cleft, the calyx five-lobed, and ten stamens. In other respects both sections are nearly alike; both have a honey-bearing disc, and both have the leaves, which are narrow and leathery, slightly rolled in at the margin. The stamens appear differently in the several genera; some being capitate, others ending in awn-shaped horns; in some they are concealed by the corolla, in others they are exposed. The style, in some of the genera, projects considerably beyond the corolla, in others it is rather contracted. The more familiar genera are, the common heath of our moors (*Erica tetralix*), common ling or heather (*Calluna vulgaris*), and the Cape heaths, many of which have glutinous, cylindrical corollas. All of these are true heaths, and bear so striking a resemblance to the common ling of our moors as to be at once recognised. The genera *Andromeda*, *Zenobia*, the strawberry-tree (*Arbutus*), the bearberry of our Highlands (*Arctostaphylos uva-ursi*), and *Gaultheria*, frequent in gardens, are illustrations of the second section. The heathworts cover large tracts of our own country, are common in North and South America, and abound at the Cape of Good Hope, which has supplied our gardens with hundreds of the most beautiful species. All of them possess bitter, astringent, and diuretic properties; and the berries of some, as well as the flowers, have been used in dyeing. The Arbutus is a very ornamental shrub, the berries of which are edible, and may be used in the preparation of a wine. The Picts are said to have derived a wholesome beverage from the heath; and the bearberry plant is used in some parts of Russia for tanning. The Highland heath furnishes excellent pasture for bees, and its shoots furnish the principal food of the grouse. 2. *Rhododendreæ.*—The plants in this sub-order have all less or more a resemblance to the well-known genus *Rhododendron*, the species of which have generally evergreen leaves, and large showy flowers produced in terminal corymbs. The calyx is small; the corolla, large in proportion, bell-shaped, and deeply five-cleft; the stamens, five or ten; the capsule, five-celled, and five-valved. The flowers are generally purple or whitish, though in some they are yellow, pink, or bright scarlet, as in the Nepaul tree-rhododendron (*R. arboreum*). The genus *Azalea* is very nearly allied to the rhododendron; but its species—the Indian and American—differ considerably in their inflorescence and leaves; the latter in some species being deciduous. *Kalmia* and *Menziesia* are familiar garden genera; *Ledum palustre*, or wild rosemary, and the Labrador tea-plant (*L. latifolium*), also rank under this section, whose members have an extensive range, being found abundantly in Europe, Asia, and North America. They are chiefly inhabitants of high cold regions, and in this particular agree with the general habit of the order. The Rhododendra possess soporific properties—*R. crysanthum* being used in gout and acute rheumatism. The Azaleas are astringent, and some yield a poisonous honey, well distinguishing these plants from the true heaths, none of which are poisonous. The honey which gave rise to symptoms of poisoning in the Greek soldiers during the celebrated Retreat of the Ten Thousand mentioned by Xenophon, was obtained from *Rhododendron ponticum* and *Azalea pontica*, two ornamental shrubs much cultivated in our gardens and shrubberies. The late Colonel Madden observed, that the leaves and flowers of *R. arboreum*, in like manner, poisoned the cattle which partook of them in Kumaon. Other species are poisonous, while some yield a resinous matter having a powerful and oppressive odour. *R. setosum* is the *Tsalu* of the Sikkim Bhoteas and Tibetians, who attribute the oppression and headaches attending the crossing of the loftiest passes of the Eastern Himalaya to the strongly resinous odour of this and *R. anthopogon*, the *Palu* of the natives. The Rhododendrons recently introduced by Dr Hooker from Sikkim form the most valuable addition to our ornamental plants that has been made for many years. *R. nivale*, which occurs at elevations of from 16,000 to 18,000 feet on the Tibetan frontier, is thus described: 'The latest to bloom, and earliest to mature its seeds, by far the smallest in foliage and proportionably largest in flower, most lepidote in vesture, humble in stature, rigid in texture, deformed in habit, yet the most odoriferous, it may be recognised, even in the herbarium, as the production of the loftiest elevation on the surface of the globe—of the most excessive climate—of the joint influences of a scorching sun by day, and the keenest frost at night—of the greatest drought followed in a few hours by a saturated atmosphere—of the balmiest calm alternating with the whirlwind of the Alps. For eight months of the year it is buried under many feet of snow; for the remaining four it is frequently snowed and sunned in the same hour.' 3. *Pyroleæ.*—This sub-order is well illustrated by the winter-green (*Pyrola*), which is common in British woods. The species of Pyrola are described as 'pretty little evergreen plants, with white flowers, the corollas consisting of five distinct petals, and which have ten stamens, the anthers of which are two-celled, each cell opening by a pore: the style is single, ending in a capitate stigma cut into five lobes; the fruit, a five-celled capsule.' They are chiefly objects of interest to the practical botanist.

OLEACEÆ.—Under this order are reckoned upwards of 20 genera, and about 130 species. They are trees and shrubs with erect or climbing stems, and with leaves opposite, petiolate, simple, seldom ternate or pinnate, and destitute of stipules. The inflorescence is often paniculate; the flowers regular, and sometimes, by abortion, polygamous; calyx, free, divided, and persistent; corolla, hypogynous, four-cleft, and rarely wanting; stamens, two, alternating with the lateral lobes of the corolla when present, or when there are four petals connecting the lateral petals in pairs; filaments, free; anthers, two-celled, bursting longitudinally; ovary, free, two-celled; ovules, pendulous and in pairs; style, sometimes wanting; stigma, entire or bifid; fruit, fleshy or dry, sometimes one-celled by abortion. According to the character of the fruit, the order is sometimes subdivided into the OLEÆ, having it a drupe or berry, and the FRAXINEÆ, having it samaroid.

The principal genera are—*Olea*, the olive; *Fraxinus*, the ash; *Ornus*, the manna-ash; *Ligustrum*, the privet; *Syringa*, the lilac; *Chionanthus*, the fringe-tree; and *Phillyrea*. The olive (*O. Europæa*) is a well-known tree, with small white flowers, and a fleshy drupe like a sloe, from which is expressed the olive oil of commerce. The

ash (*F. excelsior*) is a common British tree, with pinnate leaves, the flowers without a corolla, and the fruit a winged samara or key, with one or two seeds. The manna-ash (*Ornus Europæus*), though closely resembling the common ash in its leaves and samara, has loose panicles of white flowers, the corollas of which are divided into four long narrow segments. The privet (*Ligustrum vulgare*), the lilac (*Syringa vulgaris*), and Phillyrea, are too common ornamental shrubs to require particular notice.

Economically, the oliveworts are of great importance. Besides the oil of the olive, so universally used in Europe, the unripe berries are pickled and eaten on the continent to provoke an appetite; and the bark, which is bitter and astringent, is used as a substitute for cinchona. The bark of the common ash, as well as that of several others, is astringent and febrifugal, while the wood of the former is easily worked, and exceedingly tough and durable. What is in the present day called manna is a saccharine cathartic, procured by wounding the bark of the Ornus, &c. The sweetness of this substance is not due to the presence of sugar, but to a distinct principle called Mannite, which differs from cane-sugar in not fermenting with water and yeast. The lilac, like the ash and others, is held in great repute in some of the marshy districts of France as a febrifuge, being indeed the only remedy ever employed for the marsh or intermittent fever which prevails there. The flowers of *O. fragrans* are said to be employed by the Chinese to impart a delicate flavour to some of their teas.

APOCYNACEÆ.—Trees or shrubs, usually with milky juice, and characterised by their peculiar hour-glass-like stigma. It contains about 600 species. *Vinca minor* is a familiar British representative, being one of the prettiest wild-flowers of our woods; while more gorgeous species of *Allamanda* and *Nerium* luxuriate in warmer regions. *Cleghornia*, and many others, occur in India. Mr Paul speaks of the *Nerium Oleander* as the great ornament of the banks of the Jordan, where he observed it in 1856 in immense profusion. The remarkable structure of its stomata is described under VEGETABLE PHYSIOLOGY (p. 71), but all the order do not present this peculiarity. Its wood is poisonous, and has proved fatal when used as skewers in camp-cooking.

LOGANIACEÆ.—This order consists chiefly of woody plants, with opposite entire, stipulate leaves, natives of the tropics. It is chiefly remarkable from containing *Strychnos Nux-vomica*, the plant from which strychnine is prepared. It is called rat's-bane, poison-nut, or koochla. This tree abounds on the Malabar and Coromandel coasts of the Indian peninsula, and produces a small orange-like fruit full of pulp, in which the seeds are imbedded. The latter alone form the fatal drug; but the wood of the tree is intensely bitter, and is employed in the cure of intermittent fevers and the bites of venomous snakes. Strychnia, the alkaloid upon which the poisonous properties of the seeds depend, is an intensely bitter substance—so bitter, says Johnston, that its taste can be detected when dissolved in 600,000 times its weight in water. This has led to its use in the adulteration of malt liquors, and there is reason to believe that it is still used for this purpose. *S. toxifera*, another species, is employed by the Red Indians to poison their arrows, which thus cause immediate death when introduced into the slightest wound. *S. Tieuté* yields the upas radja of Java, not that half-mythical upas around which so many fearful *fables* have been entwined.

CONVOLVULACEÆ.—A well-defined order, containing above 40 genera, and between 600 and 700 species. The members are lactescent herbaceous plants or shrubs, with stems usually twining, and with leaves alternate, undivided or lobed, and exstipulate. The inflorescence is axillary or terminal; peduncles one or many flowered, the partial ones generally with two bracts; calyx, persistent in five divisions, and imbricated as if in more whorls than one—often very unequal; corolla, monopetalous, hypogynous, regular, deciduous; the limb, five-lobed and plaited; stamens, five, inserted into the base of the corolla, and alternate with its segments; ovary, free, with two or four cells; the ovules, definite and erect; style, one, usually divided at the top; stigmas, obtuse or acute; capsule, with the valves fitting at their edges to the angles of a loose dissepiment, bearing the seeds at its base; seeds, large; albumen, mucilaginous.

The more familiar genera are *Convolvulus* and *Ipomœa*, which have the corolla marked with a decided fold or plait, peculiarly imbricated calyx, and are climbing plants, not easily confounded with any other family. The *Convolvulus arvensis* is the wild climber of our hedges; and *C. tricolor*, so common in gardens, is a native of Sicily. The bindweed (*Convolvulus Sepium*) is another of our hedge-natives, and is a well-known pest of the farm.

The roots of the order abound in an acrid, purgative, milky juice, exemplified in *jalap*—which is obtained from *Exogonium Purga*—and in *scammony*, the concrete juice of the root of *Convol. scammonia*, the roots or tubers of *Convolvulus Batatas*, the common sweet potato, are edible, as are also those of *Ip. macrorhiza*, whose insipid farinaceous tubers are found in the sandy soil of Georgia and Carolina, weighing as much as forty or fifty pounds.

CUSCUTACEÆ.—These plants are parasitical, and are very destructive to flax and clover crops in England, some of them having been originally introduced with the seed of these crops from Odessa and elsewhere.

BORAGINACEÆ.—The plants of this order are chiefly herbaceous, have round stems, alternate rough leaves, and flowers in scorpioidal cymes. Corolla, usually regular and five cleft, imbricate, often with faucial scales. Fruit, two or four distinct achenes; seeds, exalbuminous. Some of the plants of the order yield dyes, such as the alkanet, others form pot-herbs; one maritime species (*Stenhammaria*) is a vegetable substitute for oysters, having, it is said, a similar flavour; and another (*Symphytum asperrimum*) is particularly recommended by agricultural writers as a suitable food for pigs. More sentimental associations surround the forget-me-not (*Myosotis palustris*), which is not uncommon in marshy situations in many parts of Britain.

NOLANACEÆ, SOLANACEÆ, ATROPACEÆ.—These three groups have, until lately, been associated under one order; and although tabulated separately, we shall save space by discussing their characteristics together, for they have many points of structure in common. They are herbaceous plants or shrubs, with alternate leaves, and with angular or rounded stems; calyx, five (rarely four), parted and persistent; corolla, with the limb having the same number of lobes as the calyx, somewhat unequal, and deciduous; estivation, folded or imbricate; stamens, alternating with the segments of the corolla, sometimes one abortive; anthers, bursting longitudinally, or by terminal pores; ovary, two or more celled, rarely one-celled; ovules, usually indefinite; style, continuous; stigma, obtuse, very rarely lobed; fruit, either a capsule opening variously, a berry with the placenta adhering to the dissepiment, or a nuculanium, with five spurious-celled nucules, which have one seed in each; seeds, sessile.

The *Solanaceæ* closely resemble each other in their flowers, of which those of the garden nightshade and potato may be taken as examples; and also in their berry-like fruit, which is always crowned by the persistent calyx; seeds, albuminous; embryo, curved. The genus *Solanum*, to which belongs the bitter-sweet (*S. Dulcamara*), the garden nightshade (*S. nigrum*), and the potato (*S. tuberosum*), has the anthers opening by two pores like the heaths; whereas all the other members have a slit down each cell, as the tomato, or love-apple (*Lycopersicum esculentum*), with its edible fruit; the capsicum (*C. frutescens*, &c.), whose dry inflated berry yields the cayenne-pepper of commerce;

and the winter-cherry (*Physalis Alkekengi*), also with edible berry-like fruit. To the *Atropaceæ* belong the deadly nightshade (*Atropa Belladona*), which furnishes the deadly poison of that name; and the Barbary or box-thorn (*Lycium barbarum*). They are dangerous in their qualities, the leaves and flowers being narcotic and poisonous. They are distinguished from the preceding by the imbricated estivation of the corolla, and their fruit is usually capsular and hard when ripe, and not soft and pulpy like a berry. The flowers are also more funnel-shaped, with a longish tube and spreading limb. The principal genera are—*Nicotiana N. Tabacum*, being the Virginian tobacco of commerce; *Petunia*, which furnishes some of our best known garden favourites; *Nierembergia*, a genus of ornamental green-house plants; *Hyoscyamus*, the poisonous henbane; *Datura*, *D. Stramonium*, being the common thorn-apple; and *Brugmansia* and *Salpiglossis*, all more or less prized for their showy funnel-shaped flowers, some of which are highly fragrant. The plants of this order display marked narcotic properties, and cause dilatation of the pupil: according to Dr Anderson, the true Solanaceæ do not cause dilatation. *Nolanaceæ*.—'This tribe,' says Mrs Loudon, 'is principally known by the genus *Nolana*, the species of which are annual plants, natives of Chili and Peru, which have of late been much cultivated in British gardens. The flowers of *N. atriplicifolia*, one of the commonest kind, very much resemble those of the *Convolvulus tricolor*, and the leaves are large and juicy like those of the spinach. On opening the corolla there will be found five stamens, surrounding four or five ovaries, which are crowded together on a fleshy ring-like disc. These ovaries, when ripe, become as many drupes, enclosing each a three or four celled nut, which is marked with three or more grooves on the outside, and has three or more little holes beneath. All the species of Nolana have the same peculiarities in their seed-vessels, though they differ in many other respects.'

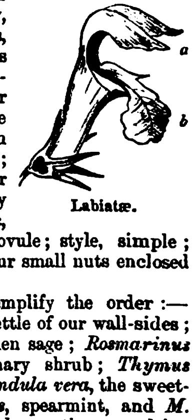
SCROPHULARIACEÆ.—The Figworts, of which the common foxglove may be taken as the type, form rather an extensive order, consisting of about 170 genera, and 1800 species. The members are herbaceous, rarely shrubby plants, with round or square stems; the leaves being simple and exstipulate, opposite or whorled, seldom alternate, and either sessile or with footstalks. The inflorescence is very variable, being axillary or united, usually in spikes, racemes, or in panicles; calyx, inferior, persistent, and often unequal; corolla, tubular or inflated, with a short limb, which is flat or erect, nearly equally divided, or labiate; stamens, definite, two or four; filaments, free; anthers, two-celled; ovary, two-celled and many-seeded; style, simple; stigma, obtuse, rarely bifid; fruit, a dry capsule.

Foxglove.

The following genera may be mentioned as illustrative of the order:—*Scrophularia*, weeds common in British ditches; *Digitalis*, the foxglove of our waysides and gardens; *Antirrhinum*, the well-known snap-dragon; *Linaria*, the toad-flax of our hedges and banks; *Euphrasia*, the eyebright; *Veronica*, including the brooklime of our ditches, and the speedwells, which abound in every waste place; *Rhinanthus*, the yellow rattle; and *Calceolaria*, *Buddlea*, *Mimulus*, and others, now favourites in every flower-garden. The form of the flowers in the different genera varies considerably, as may be seen by examining the foxglove, the speedwell, and calceolaria—plants at the command of every one. The stamens also present considerable differences: in the foxglove (*Digitalis purpurea*) there are two long and two short; in *Pentstemon* there are five, the fifth being long and slender, and without an anther; in *Calceolaria* and *Veronica* there are only two. Various attempts have been made to subdivide the order—as, for example, into two sections, the one including the genera having four anther-bearing stamens, and the other those having only two-anthered stamens. Mr Bentham divides it into three sub-orders, according to the inflorescence, each of which is again subdivided into several tribes.

In their properties, the members of this family present no great uniformity. The majority, however, contain a principle more or less acrid, purgative in some, and poisonous, as in the foxglove, unless taken in small doses. The meadow eyebright (*Euphrasia officinalis*) is slightly astringent and aromatic, without the deleterious qualities of the other genera. Cows are said to be fond of *Melampyrum pratense;* and Linnæus says the best and yellowest butter is made where it abounds. One or two species of Linaria and Calceolaria are named as yielding colours for the dyer. *Mimulus luteus* affords an interesting example of an exotic plant—from America—becoming speedily diffused throughout Europe in a naturalised state. It is now not uncommon in ditches. Its stigma, formed of two lips, displays peculiar irritability.

LABIATÆ.—A very large natural order, remarkable for the uniformity of structure and properties which prevails among the members. The *labiate* or lipped corolla immediately suggests the mint, sage, thyme, dead-nettle, horehound, and lavender, with which every one must be more or less familiar. They are herbs or under-shrubs, with quadrangular stems, and opposite, divided or undivided, exstipulate leaves, replete with receptacles of aromatic oil. The flowers are in opposite, nearly sessile, axillary, verticillasters, resembling whorls, as in the dead-nettle; sometimes solitary; calyx, tubular and persistent; corolla, bilabiate, the upper lip (*a*) being entire or bifid, the lower (*b*) three-cleft, the upper in estivation overlapping the lower; stamens, four, didynamous, the upper sometimes wanting; ovary, deeply four-lobed, seated on a fleshy disc, each lobe containing one erect ovule; style, simple; stigma, bifid; fruit, from one to four small nuts enclosed within the persistent calyx.



Labiatæ.

The following plants well exemplify the order:—*Lamium album*, the white dead-nettle of our wall-sides; *Salvia officinalis*, the common garden sage; *Rosmarinus officinalis*, the well-known rosemary shrub; *Thymus vulgaris*, the garden thyme; *Lavandula vera*, the sweet-scented lavender; *Mentha viridis*, spearmint, and *M. piperita*, peppermint; *Nepeta Glechoma*, the ground ivy of our woods and hedges; *Marrubium vulgare*, the true medicinal horehound; *Ballota nigra*, black horehound, well known for its heavy oppressive smell; *Prunella vulgaris*, self-heal; *Ajuga reptans*, the common bugle of our woods and shady situations; with basil, marjoram, betony, hyssop, and other culinary and medicinal herbs.

ACANTHACEÆ.—There are nearly 100 genera enumerated under this order, and upwards of 1400 species of herbs and shrubs, principally inhabiting tropical regions. Leaves, opposite, and without stipules; inflorescence, terminal or axillary; flowers, showy, in spikes with two or three bracts to each; calyx, in four or five divisions, and persistent—but in many of the species inconspicuous or obsolete, its place being supplied by the large bracts; corolla, monopetalous, and usually irregular, with the limb ringent or bilabiate, and deciduous; stamens, two or four, and in the latter case didynamous;

anthers, one or two celled, sometimes bearded, as in Acanthus, and bursting longitudinally; style, simple; stigma, one or two lobed; fruit, a two-celled capsule, elastically two-valved; seeds, supported on a filiform podosperm. The elastic dehiscent capsules, wingless seeds with hooked dissepiments, and imbricated flowers, are distinguishing features.

Examples of the genera are—*Acanthus*, *Thunbergia*, *Goldfussia*, *Lankesteria*, *Ruellia*, and *Justicia*. The species of Acanthus are found chiefly in the south of Europe; they are plants with graceful foliage, and the leaves of the *A. mollis* is said to have furnished Callimachus with patterns for the capital of the

Acanthus.

Corinthian pillar. The corolla varies considerably in the different genera; being bilabiate in Justicia, funnel-shaped in Ruellia, and campanulate in Thunbergia, the species of which are exotic climbers.

The properties of the order are little known. The Arabs use the leaves of an Acanthus by way of salad; *Justicia pectoralis*, boiled in sugar, yields a sirup used in the West Indies as a stomachic; and *J. paniculata* is said to be the basis of the famous French tonic, *Drogue Amère*. A valuable deep blue dye is said to be obtained from one of the East Indian Ruellias. Some of these, as well as the Justicias, are cultivated as exotic ornamental plants.

MONOCHLAMYDEÆ.

The plants in this division have either no floral envelope, or have one only. In the former case, the pistil and stamens are naked; in the latter, they are surrounded by a calyx, there being no parts corresponding to the petals of a true corolla. The following are the orders :—

ANGIOSPERMÆ.

Nyctaginaceæ — Marvel of Peru order.
*Amaranthaceæ—Amaranths.
*Chenopodiaceæ—Goosefoots.
Basellaceæ—Basella order.
*Scleranthaceæ—Knawel order.
Phytolaccaceæ—Phytolaccads.
Petiveriaceæ—Petivera order.
*Polygonaceæ—Buckwheats.
Begoniaceæ—Begoniads.
Lauraceæ—Laurels.
Atherospermaceæ — Plume Nutmegs.
Myristicaceæ—Nutmegs.
Monimiaceæ—Monimia order.
Proteaceæ—Protea order.
*Elæagnaceæ—Oleaster.
Penæaceæ—Penæa order.
*Thymelæaceæ—Mezereons.
Aquilariaceæ—Aquilaria order.
Chailletiaceæ—Chailletia order.
Samydaceæ—Samyda order.
Homaliaceæ—Homalium order.
*Santalaceæ—Sandal-woods.
*Aristolochiaceæ—Birthworts.
Nepenthaceæ—Pitcher plants.
Datiscaceæ—Datisca order.
*Empetraceæ—Crowberries.
*Euphorbiaceæ—Spurgeworts.
Scepaceæ—Scepa order.
*Callitrichaceæ—Starworts.
*Ceratophyllaceæ—Hornworts.
*Urticaceæ—Nettleworts.
Artocarpaceæ—Bread-fruits.
*Ulmaceæ—Elms.
Stilaginaceæ—Stilago order.
Lacistemaceæ — Lacistema order.
Podostemonaceæ—River-weeds.
Chloranthaceæ—Chloranthads.
Saururaceæ—Lizard's tails.
Piperaceæ—Peppers.
*Myricaceæ—Gales.
*Salicaceæ—Willows.
Liquidambaraceæ—Liquidambars.
*Betulaceæ—Birches.
*Corylaceæ—Hazels and Oaks.
Casuarinaceæ—Beefwoods.
Platanaceæ—Plane-trees.
Juglandaceæ—Walnuts.
Garryaceæ—Garrya order.
Rafflesiaceæ—Rafflesia order.
Cytinaceæ—Cistus Rapes.
Balanophoraceæ—Balanophora order.

GYMNOSPERMÆ.

*Coniferæ — Pines or Cone-bearers.
*Taxaceæ—Yews.
Gnetaceæ—Jointed Firs.
Cycadaceæ—Cycads.

Chenopodiaceæ. — Chiefly herbs with herbaceous (greenish) flowers. The embryo is coiled round mealy albumen or spiral without albumen; ovary, free, one-celled; stamens, inserted into the base of the perianth. Many of the species are used as pot-herbs, such as Spinach, Orach, and English mercury (*Chenopodium Bonus-Henricus*). The Beet (*Beta vulgaris*) yields a large proportion of sugar, and in the form of mangel-wurzel is an important forage plant throughout Europe.

Polygonaceæ.—Chiefly herbaceous plants, with large leaves; fruit, a triangular nut; exemplified by the common dock (*Rumex*). Buckwheat (*Fagopyrum esculentum*) is cultivated in Britain as food for pheasants; and various species of *Rheum* yield rhubarb. *R. palmatum* appears to be the plant which yields the best Turkey or Russian rhubarb.

Lauraceæ.—An important order, comprising about 450 species. They are tropical trees, with elegant foliage and aromatic properties, having exstipulate, alternate (seldom opposite) leaves, with inconspicuous flowers. The perianth is from four to six cleft, the limb sometimes obsolete; estivation, imbricate. The male and female flowers are distinct; the former have four, six, or eight stamens, opposite the segments of the perianth; the latter have four or more abortive stamens, furnished with glands, but without anthers, a one-celled, one-seeded ovary, with a simple style and an obtuse-crested stigma. The fruit is fleshy and indehiscent, naked, or covered by the enlarged and fleshy perianth. The two or four celled anthers, with the valves curling upwards when ripe, like those of the berberry, and the filaments furnished with kidney-shaped glands at their base, are peculiar characteristics of the order.

The chief genera are—*Laurus*, the sweet bay; *Sassafras*, the sassafras-tree; *Persea*, the avocado-pear; *Camphora*, the camphor-tree; *Cinnamomum*, the cinnamon-tree (all of which were at one time included under the genus Laurus); *Cassytha*, *Tetranthera*, and *Cryptocarya*. The true laurels have two anthers, and naked fruit; the cassia, cinnamon, and camphor have four anthers, and the fruit covered. The plants contain essential oil in abundance, which imparts to them a peculiar sweet, though strong penetrating odour, and a warm and pleasant taste; hence they yield some of our most grateful stimulants and spices. Cinnamon, cassia, camphor, benzoin, and sassafras, are products of the family; the roots of the sweet bay yield a violet dye; and a concrete oil, used in candle-manufacture, is obtained from the fruit of *Laurus glauca*. The custom of crowning heroes and scholars with the leaves of the bay or laurel is well known to every reader of ancient history.

Aristolochiaceæ.—There are only six or eight genera in this order, the members of which are herbaceous plants or shrubs, of climbing habit. The characters are—flowers, hermaphrodite; perianth, tubular, adherent with the ovary, and divided into three segments; stamens, from six to twelve epigynous, sometimes free and distinct, in other cases adhering with the style and stigma; ovary, three to six celled; style, short; stigma, six-rayed; fruit, capsular, dry, or succulent, three to six celled, and many-seeded; seeds, thin, flat, and of a dark-brown colour.

The chief genera are—*Aristolochia*, the birthwort; and *Asarum*, the wild-ginger of North America. Many of the species are natives of Europe; but they abound

in the tropical regions of America; *Arist. Clematitis* and *Asar. Europæum* are the only two found in Britain.

Aristolochia.

The birthworts are heating and stimulating in their properties, and act chiefly on the skin and kidneys. The prepared root of *Arist. serpentaria* (Virginian snake-root) is used in ague, typhus fever, and in gout—being one of the ingredients of the celebrated Portland powder. The snake-root, as the name implies, is regarded as an antidote against serpent-bites; but whether it is or not, there can be no doubt that a drop or two of the juice, if introduced into the mouth of one of these reptiles, has the power of stupifying it, so that it can be handled with impunity; and a few drops swallowed, almost instantly causes death. The roots of the species of *Asarum* partake more of bitter and acrid properties, and have a disagreeable odour like that of the stapelias. *Asarum canadense* has an aromatic flavour, and is often used by the country people in lieu of the true ginger.

EUPHORBIACEÆ.—In Britain, this order is represented by the small weedy spurges of our gardens and waste grounds, but exhibits a nobler aspect in hot regions, where the tall cacti-like columnar species attain gigantic proportions. The juice is usually acrid and milky, and the fruit formed of three globose carpels in union. The purgative resin Euphorbium is supplied by *E. officinarum* and other species. *Hura crepitans* is the sandbox-tree, whose fruit bursts with a loud noise. *Ricinus communis* yields castor-oil. The vegetable tallow of China, which has recently been introduced to European commerce, is derived from *Stillingia sebifera*. The seeds are beaten down and boiled to separate the tallow, which fuses at 80°, and is used for candles.

URTICACEÆ—ARTOCARPACEÆ.—These are extensive orders of plants, which, to the uninitiated, may appear very dissimilar—as illustrated, for example, by the common nettle, the hop, the hemp, the pellitory of the wall, the breadfruit-tree, the cow-tree, upas, mulberry, common fig, banyan, and India-rubber tree, all of which, though exhibiting different habits and products, are not only strikingly alike in their essential characters, but also in their general properties. They are much simplified by subdivision into two orders—namely, *Urticaceæ* and *Artocarpaceæ*—the former including the herbaceous species—as the nettle, hemp, and hop, with watery juice; and the latter the ligneous species—as the bread-fruit, mulberry, and fig, which have their juice milky. Bearing this distinction in mind, the following may be stated as the characteristics common to both:—Trees, shrubs, or herbs, with alternate leaves, sometimes covered with asperities or stinging hairs, and furnished with membranous stipules, which are deciduous or convolute in vernation; flowers, usually monœcious, sometimes diœcious; perianth, membranous, lobed, and persistent; stamens, definite, distinct, inserted into the base of the perianth, and opposite its lobes; anthers, turned backwards with elasticity when bursting; ovary, superior, simple; ovule, solitary, erect, or pendulous; stigma, simple; fruit, a simple indehiscent nut, as in the nettle and hemp—or consisting of achenes immersed in a fleshy receptacle, or the persistent fleshy perianths, as in the bread-fruit, or enclosing them within its cavity, as in the fig. 'The unisexual flowers,' says Dr Lindley, 'simple lenticular fruit, and superior radicle and stipules, afford the essential characteristics of this order, which cannot well be mistaken for any except *Chenopodiaceæ;* and the plants of that order never have stipules, or rough or stinging leaves.'

The chief genera in the order URTICACEÆ are—*Urtica*, of which *U. dioica* is the common stinging-nettle of our old wall-sides; *U. urens*, the smaller stinging-nettle; and *U. pilulifera*, the Roman nettle of our gardens; *Humulus lupulus*, the cultivated hop; *Cannabis sativa*, the fibrous hemp of commerce; and *Parietaria erecta*, the pellitory of the wall. The members of this order are widely scattered over the world, and increase apparently with the progress of civilisation; some of them—as, for example, the nettles—following in the footsteps of man. The chief genera of the order ARTOCARPACEÆ are—*Artocarpus*, of which *A. incisa* is the far-famed bread-fruit of the South Sea Islands; and *A. integrifolia*, the jack-tree of the East India Islands; *Galactodendron utile*, the cow-tree or palo de vaca of South America; *Antiaris toxicaria*, the upas-tree of Java, about which so many fabulous stories have been told; *Morus*, of which *M. nigra* is the common black mulberry, *M. rubra*, the red, and *M. alba*, the white mulberry, the leaves of which are so much esteemed for feeding silk-worms; *Ficus*, of which *F. Carica* is the common edible fig, *F. Sycamorus*, the sycamore fig, the wood of which is very durable, and is supposed to have been used in the construction of mummy cases; *Urostigma*, of which *U. Indica* is the spreading banyan, and *U. elasticum*, the India-rubber tree. *Bœhmeria* (*Urtica*) *nivea*, the China nettle, is the source of that beautiful fabric for handkerchiefs, &c., which has of late years come into use under the name of China-grass and China nettle-fibre. Experiments at Kew have shewn the plant to be unsuitable for our climate; but large quantities of the fibre are produced in the East, and find a ready sale in European markets, and especially among European residents in hot countries, for whose clothing this extremely fine fibre is peculiarly adapted.

The Urticaceæ have watery juice, which is acrid and astringent, and the fibres of their stems are all less or

Hop.

more tenacious. The leaves of the hemp are narcotic; the hop has bitter, aromatic, and stomachic properties,

and its effluvia are also said to be narcotic. The stinging property of the common nettle is well known. In the Artocarpaceæ, the juice is milky, and on exposure to the air, becomes tough and elastic. Their fruit is edible, but their juice is generally acrid and poisonous; except in that of the Galactodendron, which is wholesome and nutritious. The elaboration of a tough elastic product seems to be characteristic of the whole order—making its appearance in the stem of the hemp, in the inspissated juice of the India-rubber tree, or in silk, the best of which is derived from silk-worms which feed on the leaves of the mulberry. Hemp, hops, silk, caoutchouc, figs, mulberries, and bread-fruits may be regarded as the most valuable products of the order.

Betulaceæ.—A small order of trees and shrubs, abounding in the temperate and colder regions of the globe. They have alternate simple leaves, with the primary veins often running straight from the midrib to the margin, and deciduous stipules. The flowers are in catkins, unisexual, and monœcious; the males having small scales in place of a perianth, or, in Alnus, a four-leaved membranous perianth. Stamens distinct, opposite the scales, scarcely ever monadelphous; anthers, two-celled; ovary, two-celled; ovules, definite, pendulous; style, single or none; stigmas, two; fruit, membranous, indehiscent, by abortion one-celled; seeds, pendulous, naked.

The chief genera are—*Betula*, the birch, and *Alnus*, the alder, the species of which abound in every northern country. The common white birch (*B. alba*) is an elegant tree, thriving in almost any sort of soil, and becoming stunted and dwarfish only in the arctic regions, or at great elevations. The weeping-birch is a still more graceful tree, grown in lawns and parks for its fine drooping branches and neat foliage. *B. nana* is the dwarf birch of high and exposed situations, being found on the Scottish mountains and in some countries approaching to the very limits of perpetual snow. *B. nigra* is the black birch of North America, the timber of which is used so much by cabinetmakers; and *B. papyracea* is the paper birch, whose bark is used by the Esquimaux and others in the construction of canoes. The common alder (*A. glutinosa*) is a quick-growing tree, found in swampy flats and by the borders of streams; its wood resists well the action of water, and is useful for piles; the Rialto at Venice is built on alder-piles, as well as many houses in Amsterdam; the hoary alder (*A. incana*) is seldom found south of the sixtieth parallel; the notch-leaved alders (*A. sinuolata* and *A. glauca*) are both American species.

The bark of the order is astringent and bitter, and has been used with effect as a febrifuge. A decoction of birch-bark is used by the Laplanders in the preparation of reindeer-skins; and the empyreumatic oil derived from it is said to be used by the Russians in tanning—hence the peculiar odour of their leather. The sweetish sap obtained by tapping the birch in spring is the chief ingredient in birch-wine; the leaves, which, when young, are highly odorous, are also used in imparting dyes of various shades of yellow. The wood of several of the birches is used in furniture-making and turning, and makes no mean substitute for mahogany. The wood of the alder is soft and white, and is used by turners and veneerers.

Corylaceæ.—The Corylaceæ or Cupuliferæ are so named from the cup-like shape of the persistent involucre in which their fruit or nuts are placed—as, for example, the acorn. The order includes many genera of well-known trees and shrubs—as the oak, chestnut, beech, hazel, and hornbeam. Their leaves are alternate, simple, and stipulate; their venation well marked, and often rigid; flowers, unisexual; the males in catkins, and the females in clusters or in catkins; the male flowers have from five to twenty stamens inserted into the base of the scales, or of a membranous perianth, generally distinct; in the females, the ovaries are crowned by the rudiments of an adherent perianth, seated within a coriaceous involucre of various figure, and with several cells and several ovules, most of which are abortive; ovules, twin or solitary, pendulous; stigmas, several, nearly sessile, and distinct; fruit, a bony or leathery nut, of one cell, and more or less enclosed in the involucre.

The following are the most familiar genera:—*Quercus*, of which *Q. pedunculata* and *sessiliflora* are the British oaks; *Q. suber*, the cork-tree; *Q. Ilex*, the evergreen oak; *Q. rubra*, the scarlet oak of America; and *Q. infectoria*, the gall-yielding oak. *Fagus*, of which *F. sylvatica* is the common beech of our woods; and *F. ferruginea* has edible fruit. *Castanea*, to which belong *C. vesca*, the edible sweet chestnut; and *C. pumila*, the dwarf Virginian chestnut. *Corylus*, of which *C. Avellana* is the common hazel-nut or filbert, which yields an oil used by artists and watchmakers. *Carpinus Betulus*, the humble hornbeam of our hedges; and *Ostrya vulgaris*, the hop hornbeam. The hornbeams are by some botanists ranked under the Birch tribe, on account of the involucre not forming so complete a cupule as the other genera; but this seems too minute a distinction, as the involucre is not more leafy than it is in some of the filberts. The members of the family abound in Europe, Asia, and North America, and generally in temperate regions, more sparingly in South America; they are altogether absent from the south of Africa.

The bark in all the species is bitter and astringent, and is used for dyeing, tanning, and for medical purposes. Their timber is in general employed as a durable material for house and ship building, and implement-making—as that of the oak, chestnut, and beech. In a few, the fruit is bitter and disagreeable; but in the majority it is farinaceous, and frequently contains an oily matter, used in domestic economy. Many of the lower animals derive their main subsistence from the acorns (beech-mast, chestnuts, and hazel-nuts) of this order; their fruit, as well as their bark and timber, is of the highest value to man. The gall-nut is an excrescence of the oak-leaf, caused by the puncture of an insect; it is used in medicine, and is the chief ingredient in ink and in black dyes.

Rafflesiaceæ.—Stemless and leafless parasites, the whole plant consisting of a single flower with a few scale-like bracts. Some plants of the order are of gigantic size, the flower of *Rafflesia Arnoldii*, a native of Sumatra, being capable of containing twelve pints of fluid in its cup, and attaining a weight of fourteen pounds. It grows on the roots and stems of vines (Cissus).

Coniferæ.—One of the most important, as it is one of the best defined, of the natural orders. Its members are trees or shrubs, with a symmetrically branched trunk abounding in resin, and are familiarly illustrated by the Scotch pine, the spruce and silver firs, the larch, the cedar, the araucaria, the arbor vitæ, the cypress, and the juniper. The ligneous tissue of their wood is marked with circular discs having a central punctation; their leaves are linear, needle-shaped, or lanceolate, entire at the margin. The characters afforded by the fructification are:—Flowers, unisexual; males in deciduous catkins, monandrous or monadelphous, each floret consisting of a single stamen, or of a few; females in cones, whose scales arise from the axil of membranous bracts supplying the place of ovaries; destitute of style or stigma; ovules, naked, in pairs on each scale, with large micropyles at their apices; fruit consisting of a cone formed of the hardened scales, which become enlarged and indurated, and occasionally of the bracts also; seed, with a hard crustaceous testa. In speaking of the Coniferæ, it has been not inaptly remarked that 'the flowers are quite different from what is generally understood by that name, being in fact nothing but

scales; those of the male containing the pollen in the body of the scale, and those of the female producing the ovules or incipient seeds at the base.'

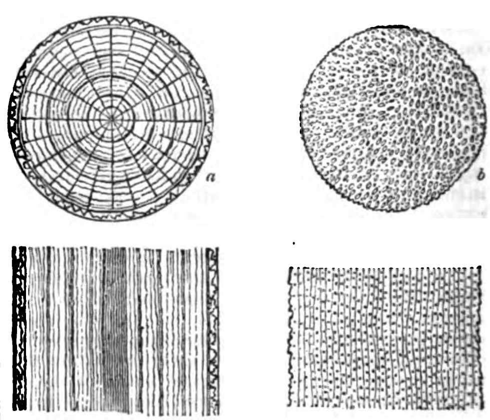
Well defined as the order obviously is, there are minor distinctions which warrant its subdivision into the following sections:—namely, ABIETINEÆ, the true pines and firs; and CUPRESSINEÆ, the cypresses. In the firs, the fruit is a cone, the scales of which open, and more or less recurve, when the seeds are ripe; the ovules are inverted; the pollen, oval, or curved: in the cypresses, the fruit is also a cone, but rounder, and with fewer scales, occasionally succulent, forming a galbulus; ovules, erect; pollen, spheroidal. In other respects—as in their foliage, habit, resinous secretions, &c.—they closely resemble each other. Of the Abietineæ the following are characteristic members:—*Pinus sylvestris*, the Scotch pine; *Abies excelsa*, the spruce fir; *Picea nobilis*, the silver fir; *Larix Europæa*, the common larch; *Cedrus Libani*, the cedar; and *Araucaria excelsa*, the Norfolk-Island pine—all of which are evergreens, with the exception of the larch. The Cupressineæ are well represented by *Cupressus sempervirens*, the evergreen cypress; *Thuja occidentalis*, the American arbor vitæ; *Taxodium distichum*, the deciduous cypress; *Juniperus communis*, the juniper of our moors; *J. sabina*, the savin-tree, as well as by the newer genera, *Saxe-Gothæa*, *Fitzroya*, &c.

The high importance of this order is derived from its timber, which in all is straight, easily worked, and durable. The *Wellingtonia gigantea* of California forms a lofty trunk ninety feet in circumference, and some other species recently introduced are not greatly inferior in point of size; but space would fail us to enumerate even the names of all the valuable additions that have of late years been made to this order, which is of so great national importance. Vast forests of pines occur in North America, which have yielded many species well adapted to our climate, such as *Abies Douglasii*, *Pattoniana*, *Pinus Balfouriana*, *M'Nabiana*, *Jeffreyi*, &c.; and indeed almost every gentleman's estate exhibits examples of this order, not only from America, but from almost every region in the world. The deodar and cedar, from the East; firs, cypresses, and junipers, from the far west; araucarias, from Chili and the antipodes; and cryptomerias, from Japan, form by far the most interesting, the most useful, and the most ornamental of our forest-trees, whether planted merely with a view to the raising of timber, or for the purpose of beautifying the landscape. (See ARBORICULTURE.) Many plants of the order are also valuable for their resinous productions; several kinds of pitch, tar, turpentine, gums, and balsams being procured from them. The large seeds of some are edible and wholesome; the succulent cones, or, as they are familiarly called, *berries* of the juniper are largely used in the preparation of gin; and the main ingredient in spruce-beer is an extract from several species of Abies. Great tanning powers exist in the bark of the larch; the savin, juniper, and others, possess stimulating and diuretic properties.

TAXACEÆ.—The yews are nearly related to coniferæ, and are usually associated with them. They differ in not producing true cones. The wood of many species is also peculiar, having spirals on the wood-cells as well as discs; but this we have recently ascertained to be also the case in some firs—such as *Abies Douglasii*, and an unknown kind of timber received from California in the form of a packing-box, which is perhaps the most beautiful of all woody tissues. The most highly prized timber of New Zealand is furnished by a plant of this order (*Podocarpus Totarra*); and species of *Dacrydium* are also valuable. In our own country, *Taxus baccata*, the yew, and many introduced species, yield excellent timber, and are also among the most ornamental evergreen trees and shrubs adapted to our climate. (See ARBORICULTURE.)

MONOCOTYLEDONOUS PLANTS.

The Monocotyledons or Endogens include those plants whose leaves have their veins placed parallel—as the palms, the grasses, the hyacinth and crocus, and whose stems have no distinction of pith, wood, bark, concentric circles, and medullary rays, like the Exogens (*a*), but consist merely of a confused mass of tissue (*b*). Their seed contains an embryo, having only one seed-lobe or cotyledon; hence the term Monocotyledon. Their trunks increase inwardly, instead of by external concentric layers; hence also the term Endogen. They are divided into three sections—DICTYOGENÆ, differing from all the others in having the leaves net-veined, and usually articulated with the stem; woody matter of the rhizome



Sections of Dicotyledonous and Monocotyledonous Stems.

disposed in wedges. FLORIDÆ, those having a perianth—such as the orchis, lily, palm, &c. GLUMIFERÆ, those which are destitute of a perianth, but have glumes or husks instead, like the grasses. The trees of this division are strictly tropical; the herbaceous species are found all over the globe.

§ 1. DICTYOGENÆ.

*Dioscoreaceæ—Yam order.
Smilaceæ—Sarsaparilla order.
*Trilliaceæ—Trillium order.
Roxburghiaceæ — Roxburghia order.
Philesiaceæ—Philesia order.

§ 2. PETALOIDEÆ.

*Hydrocharidaceæ—Frog-bits.
*Orchidaceæ—Orchids.
Apostasiaceæ—Apostasia order.
Burmanniaceæ—Burmannia order.
Zingiberaceæ—Ginger order.
Marantaceæ—Arrow-roots.
Musaceæ—Bananas.
*Iridaceæ—Iris order.
*Amaryllidaceæ — Amaryllis order.
Hypoxidaceæ—Hypoxids.
Hæmodoraceæ—Blood-roots.
Taccaceæ—Tacca order.
Bromeliaceæ—Pine Apples.
*Liliaceæ—Lilies.
*Melanthaceæ — Colchicum order.
Gilliesiaceæ—Gilliesia order.
Pontederiaceæ — Pontederia order.
Xyridaceæ—Xyris order.
Philydraceæ—Waterworts.
Commelynaceæ—Spider-worts.
Mayacaceæ—Mayaca order.
*Juncaceæ—Rushes.
Palmaceæ—Palms.
*Alismaceæ—Water-plantains.
*Juncaginaceæ—Arrow grasses.
*Butomaceæ — Flowering-rushes.
Pandanaceæ—Screw-pines.
*Typhaceæ—Bulrushes.
*Araceæ—Arum order.
*Orontiaceæ—Sweet Flags.
Pistiaceæ—Duck-weeds.
*Naiadaceæ—Pond-weeds.
Triuridaceæ—Triuris order.
*Restiaceæ—Restio order.
*Eriocaulonaceæ—Pipeworts.
Desvauxiaceæ—Bristleworts.

§ 3. GLUMIFERÆ.

*Cyperaceæ—Rushes.
*Gramineæ—Grasses.

DIOSCOREACEÆ.—These are twining, somewhat shrubby plants, with unisexual flowers in spikes, natives of the tropics, except *Tamus communis*, which represents the order in temperate climates. Various species of

Dioscorea yield edible tubers; and *D. Batatas*, recently introduced under the name of the Chinese Potato, is likely to prove a valuable addition to our garden esculents, although the hopes that have been held out of its supplanting the potato—now no longer a sure crop—may not be realised.

ORCHIDACEÆ.—This order consists of terrestrial or epiphytal herbaceous plants with enlarged roots and stems—the former in epiphytal species being clothed with an outer layer of spiral cells, which apparently serve the purpose of absorbing moisture from the atmosphere, and thus enabling the plant, which has no roots in the soil, to subsist and develop itself. The perianth consists of six segments in two rows, one differing in form from the rest, and called the labellum. The pollen-cells do not occur in the form of distinct grains, but are aggregated together in simple or compound *masses*, which become detached collectively. The flowers often imitate the forms of insects, as the bee orchis of Kent, and the more gaudy butterfly orchis of the tropics. The singular forms and intense colours of their flowers recommend these plants to the attention of horticulturists. Of the 3000 existing species, few are conspicuous for their uses. Species of *Eulophia* furnish salep; and the fragrant vanilla, used in confectionary and in the preparation of chocolate, is obtained from *Vanilla planifolia* and *aromatica*.

BROMELIACEÆ.—This family consists of about a dozen genera, and more than 170 species of plants, with scarcely any stem, and sometimes epiphytic in their habit. Their leaves are rigid, channeled, and often spiny or toothed at the margin. The perianth is tubular, its parts in two rows; the outer, or calyx, in three clefts, rigid, and persistent; the inner, petaloid and deciduous; stamens, six, inserted into the tube of the perianth; ovary, free or cohering, and three-celled; ovules, indefinite; style, single; stigma, three-parted, often twisted; fruit, capsular or succulent, three-celled, and many-seeded.

The principal genera are—*Bromelia*, the pine-apple; *Billbergia*, *Pitcairnia*, and the curious epiphyte *Tillandsia*, Spanish or Brazilian moss, or 'Tree-beard.' They are natives of moist warm climates—such as Brazil, West and East Indies; but many of them are cultivated in hothouses in Europe. All the above-named genera are common in our stoves and conservatories. The common pine-apple (*B. Ananas*) was named by Linnæus after Bromel, a Swedish botanist; and it receives its English name from the circumstance of its fruit being covered on all sides with small triangular scales, resembling the cone of a pine-tree.

The order has several important uses. The pine-apple, so much esteemed for its fine aromatic flavour, is perhaps the most delicious fruit in the world. What is called the fruit is, in fact, the fruits of the same spike cohering into one mass, by means of their succulent bracts. Several of the species are esteemed for their showy blossoms; the juice of others yields avinous liquor; and the tough leaf-fibres of many produce excellent cordage. Some of the Tillandsias, which hang their thread-like festoons from the trees of Brazil, are collected and used for stuffing mattresses, saddles, &c., making a pretty good substitute for horsehair. Most of the genera yield a fine aromatic odour; and from their habit of retaining water in the sheathing axes of their leaves, are said to be specially grateful to the traveller in the regions where they abound.

LILIACEÆ.—A very extensive, and to the florist one of the most important of the natural orders. Taking the common white lily as the type, there is a great resemblance in all the Lilyworts, not only in their habits and forms, but also in their essential characters; but botanists have somewhat perplexed themselves by subdivisions founded upon minute differences. It must be confessed that the limits of the order are not very clearly defined, and Lindley thinks it must ultimately be split up into several orders. The plants may be generally characterised as having usually scaly or tunicated bulbs; and leaves not articulated with the stem, either sessile or with a narrow petiole. In some of the genera, the flowers are erect and single, as in the tulip; in others, they are erect, but in umbels, as in the orange-lily; and in others they are in racemes and drooping, as in yucca; or single and drooping, as in the fritillary; or with the segments curved back, as in the martagon lily. Perianth, coloured, regular, and divided into six segments, occasionally tubular; stamens, six, inserted into the segments of the perianth; anthers, opening inwards; ovary, superior, three-celled, and many-seeded; style, one; stigma, simple or three-lobed; fruit, either a three-celled, three-valved capsule, or fleshy, and then occasionally tripartite. The seeds of the Asphodeleæ have a black, crustaceous, brittle testa; in the Tulipeæ and Hemerocallideæ the testa is brown and spongy.

Liliaceous.

The following plants may be mentioned as illustrative of the principal genera:—*Lilium candidum*, the white lily; *Tulipa sylvestris*, the wild tulip; *Allium cepa*, the onion; *Fritillaria Meleagris*, the fritillary; *Hyacinthus orientalis*, the garden hyacinth; *Agraphis nutans*, the harebell; *Asparagus officinalis*, the garden asparagus; *Muscari racemosa*, the grape hyacinth; *Erythronium dens-canis*, the dog's-tooth violet; *Phormium tenax*, the New Zealand flax; *Aloë*, the aloe; *Hemerocallis*, the day-lily; *Scilla*, squills; *Asphodelus*, king's spear—all of which are within the reach of every one's examination. The Lilyworts are found in every quarter of the globe, being more abundant, however, in temperate than in tropical climates, where they exist chiefly in arborescent forms.

The properties of the order, as may be expected, present considerable differences. All the Asphodeleæ contain a bitter stimulant principle and have a viscid juice, as is exemplified by the onion, garlic, leek, and chives. The roots of some are purgative, as the aloe; while those of several lilies are eaten in Siberia, as potatoes. Gum-dragon is the styptic juice of *Dracæna Draco*, a large tree; New Zealand flax is the tough fibre of the leaf of *Phormium tenax;* squills is a well-known demulcent; and the succulent suckers of asparagus are largely eaten as a vegetable. *Xanthorhœa hastile* and *arborea* are the grass-trees of New South Wales, which yield a resin used by the natives for fixing wooden handles to stone hatchets or hammers. Many of the species are cultivated solely for their fine showy flowers.

PALMACEÆ.—An important order of arborescent endogens, with lofty, usually unbranched trunks, bearing a tuft of leaves on the summit. The leaves are large, with a plaited vernation; flowers small, arranged on a simple or branched spadix, which is enclosed in a spathe bursting on the under side; florets, bisexual or polygamous; perianth, six-parted, and persistent, its parts in a double row—the three outer segments often smaller, the three inner sometimes deeply connate; stamens inserted into the base of the perianth, usually six, seldom three, and in a few polygamous species, indefinite; ovary, one or three celled; or deeply three-lobed; ovules, three, rarely one; fruit, baccate or

Palm.

drupaceous; albumen, cartilaginous, often ruminate, with a central cavity.

The principal genera are—*Cocos*, the coco-nut; *Phœnix*, the date-palm; *Sagus*, the sago-palm; *Calamus*, the common cane; *Areca*, the betel-nut; *Borassus*, the Palmyra-palm, yielding Palmyra-wood; *Ceroxylon*, the wax-palm; *Elais; Sabal;* and *Acrocomia*. They are strictly inhabitants of the tropics, to the natives of which they are undoubtedly the most useful order of vegetation.

The properties of the Palms are numerous and varied—wine, oil, wax, flour, sugar, salt, thread, utensils, habitations, and food, being obtained from numerous species. The coco-nut, sago, date, areca, betel-nuts, and palm-oil, are well-known products. *Coir*, which is worked into mats and cordage, is the dry fibrous pericarp of the coco-nut.

BUTOMACEÆ.—A small order of aquatic plants, having very cellular leaves, furnished with parallel veins, and handsome umbellate flowers of a purple or yellow colour. Calyx, three-sepaled, usually herbaceous; corolla, three-petaled and coloured; stamens, definite or indefinite; ovaries, superior, three, six, or more, either distinct or united; follicles, many-seeded; seeds, minute, attached to the whole inner surface of the fruit.

The genera are—*Butomus*, *Limnocharis*, and *Hydrochleis*, which abound respectively in the marshes of Europe, South America, and the East Indies. *B. umbellatus*, the flowering rush, is common in our ditches and by river-sides in some parts of Britain, growing from two to three feet high, with sword-shaped leaves, and umbels of rose or purplish white flowers. *Limnocharis Plumieri*, a native of Brazil, has yellow flowers, and the apex of each leaf is furnished with a curious pore, apparently for the discharge of the superabundant moisture which constantly distils from the plant. All the members are very pretty plants; the common flowering rush being universally acknowledged as one of our handsomest native aquatics.

Flowering Rush.

The order is said to possess acrid properties; and most of the species yield a milky juice. The rhizome and seeds of the flowering rush had once an officinal value.

CYPERACEÆ.—The plants in the section Glumiferæ of the Monocotyledons are destitute of a regular calyx and corolla, having instead green or brown scales to cover the stamens and pistil. The glume or chaff of the oat (see fig.), is a familiar example of this kind of envelope. The Sedges (CYPERACEÆ) and the Grasses (GRAMINEÆ) are the only orders ranking under this sub-class. We can merely glance at the latter—naming a few of the genera which lie within the inspection of every reader.

GRAMINEÆ.—One of the most important and valuable, as it is one of the most extensive, of the natural orders. According to the latest authorities, it comprehends 4000 known species, including the common grasses of our pastures, the bread-plants or cereals—wheat, barley, rye, oats, &c.—and the sugar-cane and rice. Their roots are fibrous or bulbous; their culms or stems cylindrical and hollow, except at the joints, where they become solid, the whole culm generally covered with a silicious coating; leaves alternate, and though sheathing the stem, not united round it; flowers in spikelets, and arranged in a spiked, racemed, or panicled manner. The characters of the fructification, according to Dr Lindley, are—flowers usually hermaphrodite, sometimes monœcious or polygamous, consisting of imbricated bracts, of which the most exterior are called *glumes*, the inferior immediately enclosing the stamens, *paleæ*, and the innermost at the base of the ovarium, *scales:* glumes, usually two, alternate, sometimes single, most commonly unequal; paleæ, two, alternate, the lower or exterior simple, the upper or interior supposed to be composed of two united by their contiguous margins, and usually with two keels; scales, two or three, sometimes wanting; stamens, hypogynous; anthers, feathery or hairy; pericarp, usually undistinguishable from the seed, membranous; albumen, farinaceous.

The Grasses are scattered all over the globe, and are the most directly useful of all vegetation both to man and to the lower animals. The following well-known plants may be taken as illustrative of the order:—*Triticum vulgare*, common wheat, which, according to the experiments of Fabre, appears to have originated from a small weedy grass (*Ægilops ovata*), not uncommon on the shores of the Mediterranean. *Hordeum distichum*, common two-rowed barley; *Secale cereale*, rye; *Avena sativa*, common oat; *Zea mays*, maize or Indian corn; *Saccharum officinarum*, the sugar-cane; *Oryza sativa*, rice; *Bambusa*, the bamboo; *Phleum pratense*, cat's-tail grass; *Agrostis stolonifera*, fiorin grass; *Anthoxanthum odoratum*, sweet-scented vernal grass; *Dactylis glomerata*, cock's-foot grass; *Festuca pratensis*, meadow fescue; *Lolium perenne*, rye-grass; *Briza media*, quaking grass; *Alopecurus pratensis*, meadow fox-tail grass; and *Holcus lanatus*, woolly soft grass. The cereal grains are plants of very ancient cultivation, and not being now found in a wild state, the origin of some of them is doubtful. Though allied in many respects to the Sedges, the Grasses are readily distinguished by their hollow-jointed stems, and leaves that sheathe, but do not completely surround, the stem like a tube.

Sugar-cane.

As food for man and beast, the value of this order is too well known to require more than a passing notice. Wheat, barley, oats, rye, rice, guinea-corn, millet, maize, and the sugar-cane belong to it, with the products of which every one is familiar. The straw or dried culms are used as fodder, litter, thatch, and as material for the manufacture of ladies' bonnets. All the Grasses—from the bamboo and sugar-cane to the common rye-grass—have a thin silicious coating on their stems, which seems intended to furnish them with greater strength and durability than could have been procured by simple ligneous fibre.

CRYPTOGAMS, OR ACROGENS (FLOWERLESS PLANTS).

This class of vegetation is readily distinguished by none of its members bearing proper flowers—hence the terms *Cryptogamia* and *Flowerless*. The higher forms exhibit a peculiar kind of tissue, called scalariform vessels, as well as spiral vessels; but the lower forms consist of cellular tissue only. They exhibit very different

degrees of organisation—the highest (*ferns*) having both stems and leaves, and the lowest consisting of simple-jointed threads, or even mere individual cells. Between these two extremes there are various conditions of stem and leaf—the two most frequently graduating into each other, and forming neither true leaf nor stem, but thin expansions, termed *thalli*. Cryptogamic plants do not originate from seeds, containing embryos, like the flowering-plants, but are reproduced by means of spores—bodies which in their simplest form consist of a single cell, but which are very varied in morphological character in different families.

§ 1. ACROGENÆ.

*Filices—Ferns. *Equisetaceæ—Horse-tails.
*Lycopodiaceæ—Club-mosses. *Bryaceæ—Mosses.
*Marsileaceæ—Pillworts. *Hepaticæ—Liverworts.

FILICES.—In this order the different parts of the plant spring from a *rhizome*, or root-stock; the elegant fronds or leaves being either separate and independent, or uniting by their stalks so as to form a sort of trunk, as in the tree-ferns. The fronds are furnished with forked veins, and are usually pinnatifid, and more or less compound; sometimes nearly simple and entire; in their vernation they are circinnate—that is, they unroll from the stem outwards in the form of a crozier. The reproductive organs appear on the mature plant in the form of *sori*, or brown membranous-looking spots, usually either upon the backs of the fronds, or on their margins. These sori either lie under a small shield-like *indusium*, or they are naked; or they are arranged along the margin of the leaf, which curls over them, and supplies the place of the indusium. Each sorus consists of a number of brownish bodies, called *thecæ*, each being in reality a case containing a number of minute *spores*, which are the true reproductive bodies. (For details of the development of these spores into plants, see VEGETABLE PHYSIOLOGY, page 75.)

The Ferns are divided into the following sub-orders:—1. POLYPODIACEÆ; sporangia in variously shaped sori on the back or margin of the frond, each having an elastic ring or rachis (vertical and incomplete, or horizontal and complete), by means of which the ripe sporangium is torn so as to set the contained spores free. 2. OSMUNDACEÆ; sporangia on a transformed contracted frond, with a terminal or dorsal ring more or less complete, reticulated, and opening vertically. 3. OPHIOGLOSSACEÆ; sporangia in spikes, sessile on a contracted frond, exannulate, two-valved (vernation of frond straight). 4. DANÆACEÆ; sporangia dorsal in masses, exannulate, splitting irregularly by a central cleft. The first sub-order is illustrated by the following genera:—*Polypodium*, the polypody, which has naked sori; *Lastrea*, the shield fern; *Cistopteris*, the bladder fern; *Asplenium*, spleen-wort; *Pteris*, the common brake; *Athyrium*, to which belongs the lady fern of our woods; *Adiantum*, maiden-hair; and *Scolopendrium*, hart's-tongue, the frond of which is tongue-shaped and simple. The second sub-order is represented by *Osmunda*, the flowering fern; *Anemidictyon*, and *Lygodium*, the climbing fern. The third sub-order contains *Botrychium*, the grape fern; and *Ophiglossum*, the adder's-tongue; and the fourth, a few exotic genera. The Filices are widely distributed, delighting in humid soil and shady situations—some growing on trees.

Tree Fern.

The fronds of the family generally contain an astringent mucilage, and are thus considered as pectoral; the roots of some have recently been used successfully as anthelmintics and purgatives; and *Aspidium fragrans* has been employed as a substitute for tea. The young leaves and rhizomes of some New Zealand species are edible; and the fronds of the common brake, when burned, yield a considerable quantity of alkali.

Lycopodium (Club-mosses), Equisetum (Horse-tails), and Rhizocarpeæ (Pepperworts), are usually classed as FERN ALLIES. They display considerable variety of structure, and will well repay careful study.

BRYACEÆ.—The Mosses present many points of interest, and are daily acquiring new admirers. They are minute plants, with erect stems and small leaves, all their tissues cellular. At certain seasons, little flower-like heads are produced, some containing antheridia (so named from their resemblance to anthers), and others less conspicuous, consisting of pistillidia, which represent the female parts. At maturity, each antheridium opens at the apex, and emits a granular gelatinous mass; this consists of minute spermatozoa, which find their way into, and impregnate the pistillidia, and thus give rise to the development of the latter into an urn-shaped theca or spore-case, containing spores capable of germinating into new plants. We have stated these phenomena without an expression of doubt, because, although the act of impregnation has not been, and cannot, in the nature of things, be directly observed, the theory accords with every known fact, and is as fully proved as the present state of knowledge will permit.

Mosses grow usually in shady situations, and are abundant in wet, cold countries. Species of *Sphagnum* form peat; otherwise, their uses are unimportant. They are divided into three sub-orders—SPHAGNEÆ, ANDRÆEÆ, and BRYEÆ. Of the first, *Sphagnum*, bog-moss, is the only genus; the second is illustrated by the split-moss (*Andræa petrophila*), which is common on the Scottish hills; while the third embraces the genera *Bryum* and *Hypnum*, and most other British mosses.

§ 2. THALLOGENÆ.

The orders under the Thallogenous sub-class of Cryptogams, are—

*Lichenes—Lichens. *Algæ—Seaweeds.
*Fungi—Mushrooms. *Characeæ—Stoneworts.

LICHENES.—Lichens form not the least interesting section of the Cryptogamia, and their value on the score of utility is by no means unimportant. They are familiar objects to all in the form of apparent discolorations and incrustations on old walls and rocks; but some of them hang in festoons from the branches of trees (*Usnea*, *Alectoria*), while others (*Peltidea*) spread their thalli among mosses and herbage in shaded situations. They grow slowly, and attain an extreme age. According to Dr Lindsay, some of those growing on the primitive rocks of our highest mountain-ranges are at least a thousand years old. 'The hoary Usneas, Ramalinas, and Physcias, like the gray beard of an old man, silently but eloquently proclaim time's ravages, and illustrate the constant succession of life upon death, growth upon decay, which is going on around us.' In their reproductive organs, they approach the Fungi, but are well distinguished by the presence in their tissue of gonidia containing chlorophyll, which are capable of originating new plants.

The Lichens yield valuable dyes. Orchil, a red dye, supposed to have supplied the purple of ancient Tyre, is produced by *Roccella tinctoria*, a Southern European species which was discovered in the west of Scotland by Dr Balfour in 1855. *Cladonia rangiferina* is the Reindeer Moss, an important forage-plant in Lapland. Species of *Gyrophora* (*Tripe de Roche*) are edible, and furnished Franklin and his companions with food for many weeks in the arctic regions. Elaborate details of the much neglected uses of these plants are given in Lindsay's *History of Lichens*.

FUNGI.—The Fungi, or Mushroom family, which are among the lowest forms of vegetation, are extremely diversified in their size, shape, colour, and consistence.

The common field-mushroom is one of the best-known, and may be cited as a type of the family; but the puff-ball, truffle, morel, as well as the mould on cheese and stale bread, the mildew on trees, the rust on corn, the substance called dry-rot, and many other minute appearances of a similar nature, are all fungi. In the field-mushroom (*Agaricus campestris*), the plant consists first of some filamentous filaments or spawn, which look like roots, then the stipe or stalk, surmounted by the pileus or cup. 'When the mushroom first appears, the stalk is covered by a thin membrane, called the veil, which unites the cup to the lower part; but as the mushroom grows, this veil is rent asunder, and it either entirely disappears, or only a small portion of it remains round the stalk, which is called the *annulus*, or ring. Under the cup are gills or lamellæ, which are of a dark reddish brown; and attached to these are the thecæ, containing the spores.' Many—as the moulds, &c.—are mere microscopic jointed filaments, or filaments surmounted by little ball-like receptacles which contain the sporules, or are mere spherical or filamentous cells, which increase with astonishing rapidity, each cell containing a number of undeveloped ones.

Among the more familiar genera are—*Agaricus*, the mushroom; *Tuber*, the truffle; *Morchella*, the morel; *Boletus*, the puff-ball; *Puccinia*, the mildew; *Clavaria*, the yellow meadow fungus; *Podisoma*, the jelly-looking masses often found on juniper and savin bushes; and *Tubercularia*, the small, red, pimple-like fungus found on rotten sticks and trunks of trees. The Fungi are scattered everywhere—springing from the ground, yet without roots; under the ground, as the truffle; on all decaying organic substances; and even on living animals, as the *Achlya prolifera*, which looks like a whitish slough or slime on gold-fishes, yet is a true rapidly developing fungus. Even what we call yeast is but a spherical-celled fungus, having a nucleated development.

The plants of this order are not more diversified in form than in properties. Some are wholesome and palatable—as the mushroom, morel, truffle, &c.; others, similar to these in appearance, are deadly poisons. Many of the minuter fungi—as moulds, smuts, rusts, &c.—are noxious to the human system. Ergot forms a powerful and dangerous medicine. German tinder is prepared from a species of boletus, which, after being dried, is impregnated with nitre. The Siberian fungus is used to induce intoxication.

The vinegar plant is one of the most singular forms of fungi; it is an abnormal state of *Penicillium glaucum* developed in saccharine fluid, which it has the property of converting into vinegar of a good quality, suited for table use. It consists of a gelatinous substance of a pale brownish colour. If placed in a jar containing a solution of sugar, or a mixture of sugar, treacle, and water, and allowed thus to remain for six or eight weeks in a kitchen cupboard, the solution will be found to have become converted into vinegar; this change being due to a kind of fermentation caused by the plant. The flocculent matters which form in stale vinegar—when it becomes 'mothery'—wine, saccharine solutions, ink, &c., appear to be of the same nature.

ALGÆ.—The Algæ form a highly interesting family of plants, and are specially important to the physiologist, for it is in these that the phenomena of growth and reproduction are most successfully studied. This order —which has been wisely split up into *several orders*, concerning which our space will not permit of full details— embraces the very simplest forms of vegetation, as well as many having a complicated structure. The Algæ are not confined to the sea; many occur in fresh water and on the dry land. They are classified as follows:— 1. FUCACEÆ; brown-coloured sea-weeds. 2. RHODOSPERMEÆ; rose-coloured sea-weeds. 3. CONFERVACEÆ; green-coloured sea and fresh-water weeds. 4. DIATOMACEÆ, Brittleworts; unicellular, in the form of frustules, usually coated with silica, and containing brown, rarely green, contents. 5. DESMIDEÆ; unicellular, without silica, containing always green cell-contents. The first contains many of our large species of common sea-weeds; the second, those beautiful kinds so highly prized for albums; the third, those green filamentous species so common in stagnant waters, some of which, as the Duddingston Cladophora, fill up lakes with their interlaced masses of filaments; the fourth, those minute silicious bodies found in such amazing quantities in all parts of the world, and which often descend in showers of rain; and the fifth, the analogous non-silicious species, which display perhaps the most beautifully symmetrical forms of the vegetable kingdom.

Such, according to our limits, is an outline of the Natural System of Botany; which, though as yet but partially developed, is infinitely more interesting and instructive than any artificial method, however elaborate and complete. Undeveloped as we must admit it to be, harsh and difficult as much of its nomenclature is, unnecessarily multiplied and complicated as its orders and tribes really have been, it has still the germs of truth and nature within it, and only requires a cordial and patient elaboration, on the simple principles of its great founder, to render it what it professes to be—an exposition of the system upon which Nature has proceeded in the creation of the Vegetable Kingdom. Our brief synopsis, as contained in this and the two preceding sheets, can at most but convey to the reader a very general notion of vegetable life and relationship, and only introduce him, as it were, to the technical phraseology and mode of procedure: for further acquaintance with the subject, we cannot refer to more accessible sources than the excellent works recently published by Professor Lindley of London, and Professor Balfour of Edinburgh. There the inquirer will find, in a connected form, all that is necessary to be known in ordinary cases; there, if he is ambitious of proceeding further, he will find references to trustworthy authorities, British and continental; and there, too, he may learn the best modes of practical investigation. To observe generally, to collect everywhere, to examine carefully, and to pronounce with caution, are the duties of the true phytologist; and the more attention to these, the sooner will the objects of a Natural System be accomplished. It is true that there are some difficulties at the outset—and where is the department of human knowledge without such obstructions?—but these overcome, and what a delightful field of intellectual enjoyment beyond! The beauty and variety of flowers, the fragrance and freshness which we are insensibly led to associate with them, have long been themes for the poet and moralist, but really not more so than the subject deserves. The endless forms in which plants appear, their adaptations to certain situations, the peculiar properties which many species possess, though all grow on the same soil, the wonderful metamorphoses which they undergo from seed to plant, and from plant and flower to seed again—not to speak of the amenity and beauty with which they invest the landscape, or of the utility they confer as articles of food, medicine, and clothing— are all subjects of never-failing interest to a cultivated mind. There is, perhaps, no pursuit which leads more directly to an appreciation of that wisdom and goodness which pervade creation, than the study of the vegetable kingdom, in which infinite variety, beauty, and elegance, singularity of structure, the nicest adaptations, and the most pre-eminent utility, meet us at every step, and compel us to observe and learn, even when often the least disposed to inquiry or reflection. Take it even in the light of a mere recreation for an idle moment, it is at least an innocent and cheerful one—one that never interferes with the comfort of a neighbour, or brings to the cultivator a single feeling of mortification or regret.

ANIMAL PHYSIOLOGY—THE HUMAN BODY.

THE general aspect of animals, and the characters by which they may be ordinarily distinguished from plants, have been already adverted to under VEGETABLE PHYSIOLOGY, and need not therefore be here enlarged upon. The chief structural differences which separate the two great sections of the organic world, are those which are connected with the mode in which food is assimilated—that is, converted into the materials of their respective fabrics. Thus it may be constantly noticed that plants imbibe their nourishment either through their external surface, or by prolongations of this into roots and leaves. On the other hand, all animals, except the very lowest in the scale of organisation, possess an internal cavity, the *stomach*, into which the food is received, and where it undergoes a preparation; and the absorption of it into the system takes place by vessels distributed on the walls of this cavity, or on a tubular prolongation of it, called an *intestine*. Plants require nothing but a regular supply of water, with carbonic acid, ammonia, and a small amount of saline or earthy matters dissolved in it; and the conditions of their growth generally afford them a constant supply of these, which they can imbibe by means of their roots and leaves, without moving from the place in which they are once fixed. But animals can only be supported by materials previously organised, all their food being derived from vegetable or animal substances, generally collected by themselves, and then reduced within their stomachs to a pulp, the nutritive portion of which is absorbed in a fluid state by the tissues, and the waste rejected by means provided for that end. On the whole, though the two lines or systems of life seem to start, as it were, from a common point at the base—the inferior forms bearing a certain similarity in structure and functions—yet this similarity quickly disappears as we ascend in the scale of development, and all the vital functions of animals are performed in a manner so different from those of plants, that no one can have the least difficulty in discriminating between them. Taking the human body as that whose external configuration is necessarily familiar to all, and that whose parts are most within the scope of examination, we shall endeavour, in the present treatise, to describe the structure and functions of its numerous organs, in language as popular as the subject will permit, and as concise at the same time as possible. Though chiefly directed to the human body, notice will be taken, under the several sections, of the analogous structure and functions in the lower animals, so as to convey to the reader an outline of Animal Physiology in general, and thus prepare him for a more intelligent perusal of the succeeding numbers on SYSTEMATIC ZOOLOGY.

Zoological science places the human being in the class *Mammalia*, or suck-giving animals, and in the order *Bimana*, comprising the two-handed creatures of that class. An erect posture is the peculiar characteristic of man, and it is one which gives to his aspect that dignity becoming his high place in creation. By the adaptation of an erect structure, also, his hands are left disengaged, and ready for the numerous operations to which he is inclined by his judgment or urged by his wants. His general stature is between five and six feet. A combination of hard and soft parts forms the material of his frame, the soft portions being arranged, generally speaking, upon and around the more solid parts of the structure. These latter parts consist of a beautiful framework of bones, termed the *skeleton*, which naturally occupies the first place in our description. *Muscles* and *tendons*, which are the organs of locomotion; the *brain* and *nervous system*, or organs of sense, feeling, and intellect; the *lungs*, for respiring the air essential to the maintenance of the principle of life; the *stomach* and *digestive organs*, for the supply of nourishment; the *heart*, *blood-vessels*, and *absorbents*, for the circulation of vital fluids through the body—these, and other important parts, will fall to be described after the solid framework on which they rest has received its due share of our attention.

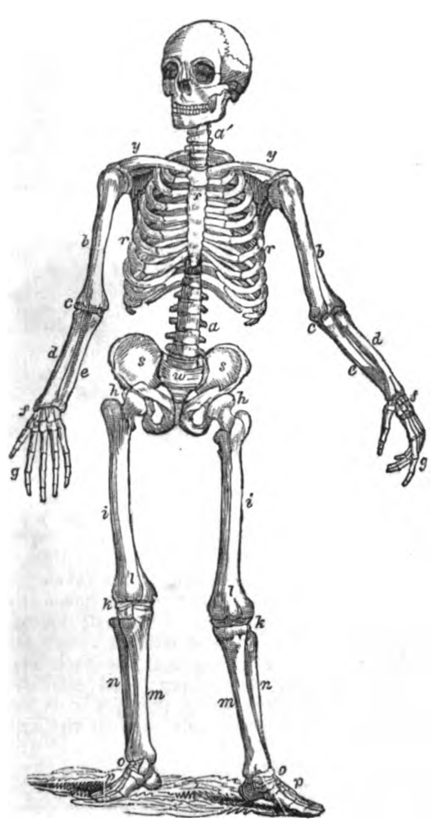
THE BONES.

The skeleton comprehends three main divisions—the head, trunk, and extremities—which consist, in all, of 254 bones, joined together in a manner combining great strength with ease and freedom of motion. The whole of the bones are composed of nearly the same materials—namely, earthy matter, chiefly lime, and gelatine or animal glue. According to Berzelius, 100 parts of human bones are composed of 51·04 phosphate of lime, 11·30 carbonate of lime, 2 fluoride of calcium, 1·20 soda and chloride of sodium, 1·16 phosphate of magnesia, and 33·30 animal matter, consisting of albumen, gelatine, and fat. This notable proportion of lime imparts to them the necessary hardness and solidity, while the animal matter cements or binds them together, and renders them not easily broken. Weighed *en masse*, a middle-sized adult skeleton ranges between 160 and 200 ounces, or from 10 to 13 pounds avoirdupois. Individually, the bones vary in solidity and weight, the heaviest in proportion to their size being those of the skull, the extremities, and the pelvis or under part of the trunk. The surface of human bone is for the most part smooth; and the interior, beneath a layer or coating of more condensed substance, is porous and spongy. The bones of the extremities in the dried condition—as ordinarily exhibited in our museums—are tubular, like pipes; but, strictly speaking, they are not hollow in the natural state, because the centre of the shaft is occupied by fatty matter, which in this situation is usually called the *marrow*. By this arrangement the bones are at once rendered light and strong; and compact as they are, they are nevertheless provided with blood-vessels, which indeed are essential to their vitality and growth.

The crown or summit of the osseous fabric is occupied by the cranium or skull, which is composed of eight bones—the *frontal*, the *occipital*, and the two *parietal*, constituting the greater part of the outward skull, before, behind, and laterally. The two *temporal* or temple-bones, on the under part of each side, and the *sphenoid* and *æthmoid* bones, placed at the base of the skull internally, are the remaining bones of the head. The union of these bones is remarkably firm and strong in the adult being. In some cases, the osseous plates are joined by serrated or ragged edges, like the teeth of a saw; in other instances, they overlap each other, like the ridge of a house—the arrangement in each case being precisely the one best fitted to insure strength and stability in the particular part. Altogether, an arch of the most powerful kind is formed, for the safe protection of the important organ within—the *brain*. The bones of the face, situated below and before the cranium, are numerous. Among the facial bones are reckoned the two upper *maxillary*, or jaw-bones; two *malar*, or cheek-bones; two *nasal*, or nose-bones; two small bones, attached to the nose internally, called the *turbinated* bones; two *palate* bones; the two *lachrymal* bones, situated in the orbit; the *vomer*, or ploughshare bone,

forming a part of the basis of the nose; and the single lower *maxillary*, or jaw-bone proper.

The bones of the skull and face rest upon the top of the spine or back-bone, which consists of twenty-four separate pieces, called *vertebræ*, firmly and curiously jointed the one into the other. The column of the spine is curved in several places, the most prominent being a curve forwards near the middle of the back. Seven of the vertebræ are called *cervical*, twelve *dorsal*, and five *lumbar*, from being situated respectively in the neck, back, and loins. Each vertebra has various projections and depressions, to admit of a firm union with those adjoining it; and by the junction of the whole, a long hollow or canal is made, for the reception of the spinal marrow. In the figure, the upper part of the



vertebral column is marked *a'*, and the lower *a*. The second of the vertebræ of the neck sends upwards a projecting pinion or tooth, which is received into a corresponding depression in the one above, thus forming the pivot upon which the head turns. A ligamentous band keeps the tooth-like projection of the second vertebra in the depression of the first; and nothing can better shew how completely our life, during every instant of its duration, depends on the maintenance of every single part, however minute, in order: if this ligament, scarcely thicker than strong paper, were to give way, instant death from pressure on the spinal marrow would ensue. The bones of the spine rest upon the framework of the *pelvis* (*s*, *s*), which is a hollow, basin-shaped cavity, formed by the approximation of two large bones, or *ossa innominata;* these constitute the lower part of the trunk, and give to it firmness and stability. The spine is fixed to the pelvis by means of the *sacrum* (*w*), a series of five imperfect vertebræ, consolidated into one piece in advanced life, which sink like a wedge between the pelvic bones of each side. The sacrum terminates in a loose osseous peak, called the *os coccygis;* this is in reality a compound bone, consisting of a chain of ossicles —three or four, and sometimes five in number—which are rudimentary vertebræ, and analogous to the more numerous tail-bones of the lower animals. The strong, hollowed innominate bones of the pelvis are marked by large round cup-like depressions on the outer and under surface of each, which form sockets for the two upper bones of the leg.

At the top of the spine, immediately below the vertebræ of the neck, are situated on each side the collar-bones, or *clavicles* (*y*, *y*), which are long and narrow in shape, and pass in a semicircle or arch from the front of the chest backwards, or, in other words, from the *sternum*, *x* (breast-bone), to the top of the shoulders. On the back of the ribs, at each side, lie the shoulder-blades, or *scapulæ*, which are thin flat bones, of a triangular shape. They rest loosely on the back, having scarcely any attachment, except by muscles, to any of the neighbouring bones. By this means they have a free and easy motion, and also communicate the same property in part to the arms, the upper bone of which is attached on each side to the scapula. A very small cavity in the latter bone admits the round ball-like head of the humerus, giving to it the most unconfined play of movement, whether of a rotatory kind, upward, downward, or sideways. Nothing can be more beautiful than the whole arrangements for permitting the arm to perform the multifarious motions which man requires from it. The *humerus*, a single bone in each arm (*b*, *b*), cylindrically shaped, is united at the elbow-joint (*c*, *c*) to the two bones of the forearm, termed the *radius* (*d*, *d*) and *ulna* (*e*, *e*). One of these, the ulna, is attached to the humerus by a hinge-joint—like that of a common door— while the radius is connected to the same bone by a round button-like head, which, being slightly concave, receives a projecting knob of the humerus, and admits of rotatory movements being performed by the lower part of the arm. These peculiarities of structure are essential to the free use of the hand. At the wrist, the position of the radius and ulna is in some measure reversed, the radius forming with the *carpal* bones (*f*, *f*) a joint like that of a door-hinge, while the ulna is in a measure left loose. The carpal or wrist-bones are eight in number. They are of small size, and lie in two rows, being jointed together in a manner that combines great strength with a certain degree of mobility. In the direction of the points of the fingers they are united with the *metacarpal* bones, forming the palm of the hand, and to which the *phalanges* (*g*, *g*), or finger-bones, are attached. Each finger has three bones in it; the thumb, or opposing finger, has only two.

As has been said, the bones of the pelvis, on each side, are marked by deep cup-like concavities, which receive the heads of the thigh-bones, *h*, *h*, *i*, *i* (*femur*), the upper bones of the lower extremities. As was required by the different nature of the purpose to be served, the ball-and-socket joint of the leg is much stronger than that of the arm, and permits of much less freedom of motion. The *femur*, or thigh-bone, is a rounded cylindrical bone, terminating at the knee in a connection with the *tibia* (*m*, *m*), the principal bone of the inferior part of the lower extremity. The knee-joint is a hinge one, but permits of a slight rotatory motion when the leg is bent. The tibia has a smaller bone, the *fibula* (*n*, *n*), placed by its side; and over the knee-joint is situated a small bone called the *patella* (*l*, *l*), or knee-pan, to which the principal muscles that move the joint are attached, and which serves to protect the parts against injury. The tibia and fibula form a union at the ankle (*o*, *o*) with the bones of the tarsus, which are seven in number, and constitute the heel or back part of the foot. These, again, are united to the *metatarsal* bones (*p*, *p*), forming the body of the foot, and five in number. To these again are joined the *phalanges* of the foot, fourteen in all, two

being attached to the great toe, and three to each of the others.

The *costæ*, or ribs (*r*, *r*), proceed from the vertebræ or back-bones, and are twelve in number on each side. They bend round in a circular manner from their point of union behind, and seven of them, called the *true ribs*, are joined directly by gristle or cartilage to the breast-bone, while the remaining five terminate anteriorly in a common cartilage, which unites with the sternum below. Altogether, the ribs form a large hollow space for the reception of the lungs, heart, and other organs, and protect them from injury. The ribs move in an easy joint formed with the back-bone, and, with the intercostal muscles, contract and expand, to suit the motions of the lungs.

These are the principal bones forming the skeleton of the human being. All animals have not this osseous framework; it is only found, and that in a modified degree, in a certain number of classes—namely, in quadrupeds, birds, reptiles, and some fishes; all of which, from the principal feature in their structure, are called *vertebrated* animals. Some of the other tribes of beings have their framework, corresponding in purpose to bones, on the outside of the body, in the form of a coat-of-mail. This is the case with shell-fish, with the crustacea, and with many insects that have a hard external covering. It is only in the skeletons of the higher vertebrata, however, that we find a real analogy to the framework of the human being. In such cases, not only are the bones of the same form and construction, but of the same number also; and where we do not find them of the same number separately, several will be discovered to have been atrophied at an early stage of existence as unnecessary to the functions of the full-grown animal, or compacted into one mass. Thus comparative anatomy detects in the foreleg of the horse, the wing of the eagle, and the paddle of the whale, the same amount of parts as are separately exhibited in the arm of man.

THE MUSCLES.

The soft fleshy substance of the body, which gives plumpness and form to the whole, is the muscular part or *muscles*. These are the instruments of motion. And when we consider the various positions which the body and its members assume, the agility and quickness with which the most intricate movements are made, the ceaseless play of the heart, the heaving of the lungs, and the singular rapidity of articulation and speech, we need not be surprised that these muscles, upon which all such movements depend, should be many in number, and be deemed agents of paramount importance in the animal economy.

The muscles are of a reddish-brown colour; they are composed of accumulated threads or fibres, arranged sometimes in layers, sometimes in a straight position, and sometimes obliquely. They are of an elastic nature, somewhat like a piece of India-rubber, and, at the impulse of the will, are lengthened and shortened alternately. A muscle is generally thick or swelled out in the middle; it gradually gets thinner towards the extremities, and in many instances passes at one or both ends into a *tendon*, or tough white substance, which is attached to a bone, and serves the same purpose as a rope or cord, to fix the muscle to the point from which it is intended to act. These tendons are most numerous about the joints, especially the larger joints, where they allow of free and unrestrained action, and yet occupy little space in situations where a large swelling muscle would have been inconvenient. About the larger joints—such as the knee, elbow, and shoulder—there are also numerous glands, which pour out an oily substance, which serves at once to lubricate the joints and facilitate the play of the tendons.

There are from four to five hundred muscles in the human body, all necessary for performing the various movements and operations of the complicated machine. On each side of the back-bone there are several layers of strong muscles, which are fixed by tendons to every projection of the numerous bones composing the spine. These muscles keep the trunk of the body erect, and also permit of the varied motions of the back. There are a multitude of small muscles about the face, head, and eyes, whose various action imparts that expression to the human countenance which indicates the prevailing feelings and passions of the individual. The tongue is also supplied by intricate muscular fibres, giving to it that amazing volubility of action by which the vast number of sounds composing language are expressed. Many are attached to the lower jaw; but two in particular, the temporal muscles, proceed upward through an arch formed by a projecting arm of the temple-bone, and are fixed to the tendons of the head. These two muscles are the most powerful in moving the jaws in the operation of chewing the food, and are very large in several animals of prey. Another flat muscle inside the cheek is called the *buccinator*, or trumpeter muscle; it is interesting to notice, as a result of its peculiar function, that this organ is especially developed in glass-blowers and individuals who play on wind-instruments. The chest is supplied with numerous muscles, which move the ribs upward and downward in the action of breathing. A large flat muscle, called the *diaphragm*, stretched across the trunk from side to side, and separating the hollow of the chest from that of the belly, also contributes mainly to the process of breathing. The arm and hand are rolled inward and outward by a set of muscles, which are placed on the outer and inner sides of the respective bones: thus the outside muscles act in a contrary manner to the inside, and reverse motions may be alternately performed. The muscles of the forearm are fixed to the scapula, or shoulder-blade, to the chest, and to the clavicle, at the upper end, and to the bone of the arm at the other. The fingers are moved by muscles situated in the forepart of the arm, and have long slender tendons by which they are attached. Two beautiful provisions of nature are here observed: at the wrist, a circular ring of tendinous substance binds down the long tendons, which would, in their various motions, otherwise start up from their places. This ring at once keeps them in place, and permits their free and unhampered play. The other provision is seen in the construction of the tendons of the fingers. There are two principal muscles which move the joints of the fingers, and two sets of tendons, which are inserted, the one into the middle bones of the finger, the other into the third row of bones, or the extremities of the finger. In order to preserve their free action, and to make them lie in the most convenient manner, there is a loop or slit in the shorter tendon, by which the other passes through to its insertion in the point of the finger. By this means, the longest and strongest muscle moves the extremities of the finger where the greatest power is wanted, without impeding the action of the other. The muscles which move the lower extremities are thicker and more powerful than those of the arms. Several large muscles, acting in opposition to each other, are situated around the thigh-joints, and move them. They are fixed, one end to the trunk of the body, some pretty far up, especially two, which are spread upon the front of the abdomen or belly, on each side of the spine, while the other ends are attached to the thigh-bone. Several thick muscles, also, are situated at the back of the trunk. Two large muscles compose the calf of the leg, and join to form the tendon of Achilles, which is fixed to the heel-bone; these muscles act powerfully in bending the ankle, and in supporting the body in walking. The foot and toes are moved by several long slender muscles situated in the leg, which have tendons attached to them, and terminating on the toes, exactly similar to those of the hand and fingers.

The pelvis and lower limbs of man differ greatly from those of all other animals, in their superior proportional

strength, and in the number and fulness of the muscles. This was necessary, as man has been evidently intended by nature for the erect position. In the monkey tribe, whose general form approaches nearest to that of man, the narrowness of the pelvis or hip-bones, and the smallness of the muscles of the lower extremities, clearly shew that they were not destined by nature for the erect attitude; in fact, all animals of this class are furnished with four *hands* or *paws*, the hinder pair exactly resembling those in front. When they attempt to walk on the hind extremities, they cannot put the sole to the ground, but press on it edgeways. By the nice balancing of the muscles, and the great force which they exert, man is enabled to stand erect, and to maintain a firm position, or move forward at pleasure, notwithstanding that the body diverges from the perpendicular line of the centre of gravity. The head is also balanced upon the neck by means of strong muscles, whose constant, though unobserved, exertion is necessary to maintain it in its position; for in young children, when the muscles are as yet weak, and in persons asleep, the head has an inclination to droop, and in the dead body it falls down on the shoulder or breast. The muscles of the neck, therefore, may be said to exercise a power in some degree involuntary, or not under the command of the will, as the majority of the muscles of the body are. But there are other muscles still more distinctly removed from under the guidance of the will. The heart is nothing else than a hollow muscle, which contracts and expands without the consciousness of the being; and, in like manner, the muscles which perform the act of respiration or breathing are not moved by the will.

This division of the muscles into two classes—*voluntary* and *involuntary*—shews, as perfectly as anything could do, the care with which our frame is constructed. Had those muscles on which respiration and the action of the heart depend been placed under the control of the will, their functions would have been liable to be impeded at every turn by circumstances. Now, these organs cannot cease to act for the most trifling interval without fatal consequences. The arrangement, therefore, which renders their operation involuntary, is one to be admired, as essential to life and comfort.

THE BLOOD—BLOOD-VESSELS.

The blood is the medium by which all the solid and fluid parts of the body are supplied with their due nourishment. In its composition, therefore, will be found the majority of the substances of which the body is composed. The blood consists of a solid coagulable matter, called *fibrin;* of a series of *red globules* which form the colouring matter; and of *serum*, or whey-like matter, consisting of albumen and salts, the latter being held in solution; it is this matter which imparts to the blood its necessary fluidity. The following chemical analysis shews, according to Lehmann, the relative proportion of constituents found in a *thousand parts* of blood:—

Water,		795·45
Fibrin,		2·025
Corpuscles	Hematin, including iron,	8·375
	Globulin and cell membrane,	141·110
Albumen,		39·420
Fatty matters,		2·015
Extractive matters,		3·270
Chlorine,		2·665
Sulphuric acid,		·090
Phosphoric acid,		·663
Potassium,		1·825
Sodium,		2·197
Oxygen,		·535
Phosphate of lime,		·212
Phosphate of magnesia,		·148
		1000·000

From the heart, the centre of the circulation, this highly complex fluid is conveyed through the body by vessels called *arteries*, and is brought back to the same part by *veins*. The purpose of its thus making the circuit of the whole body, is to supply the necessary materials for increasing the bulk and repairing the daily waste which takes place by perspiration and the perpetual operation of the numerous excretory organs. The blood is restored to its nutritious state by the *chyle*, a juice formed in the stomach and intestines from the digested food: this chyle reaches the heart by one of the large veins called the left subclavian; from the right side of the heart it goes along with the venous blood to the lungs, and there it is mixed with the oxygen, or vital portion of the atmospheric air, by which process it is converted into bright-red arterial blood. In short, there are two distinct circulations of the blood in the system. By the one, the blood is conveyed and distributed over all parts of the frame, imparting, at every pulsation of the heart from which it issues, new life and nourishment to the whole. After traversing the body, it returns to the heart, deprived of its nutritious properties, and changed in colour from a bright to a dark red. Here the second circulation, which is through the lungs, commences. The blood is poured from the right side of the heart, which has divisions for the purpose, into large vessels which carry it to the lungs, and spreading out into countless branches, penetrates and permeates their whole substance. Collected again by other vessels of equal number and extent, it is conducted by them to the left side of the heart, to be propelled anew through the frame, restored to its bright-red hue, and repossessed of all its vivifying qualities. Both these changes are effected in the lungs. The *chyle*, which may be called the essence of our food in a liquid state, is conveyed from the stomach and intestines through the chest by a duct, which empties itself into one of the veins, immediately before the blood is transmitted through the lungs. It is in these organs that the chyle is thoroughly mixed up with the circulation; and it should be remembered that this chyle is the only benefit, the only real food, extracted from all the substances received into the stomach, the remainder being entirely useless and excrementitious. From the chyle comes the material of the bones, of the fleshy or muscular parts, of the brain and nervous cords, of the hair, nails, enamel of the teeth, and, in short, of every different structure of the system. The average quantity of blood contained in an ordinary-sized person is calculated at about thirty pounds' weight. The coloured globules of blood do not enter into the smallest vessels of the body, but only the thinner part of it, which has no colour; thus in the eye there are numerous blood-vessels, but these are so minute as not to admit the red parts of the blood; and this is a necessary provision of nature, in order that these organs may retain their pure transparency for the purpose of vision. In inflammation of the eyes, when these vessels are much enlarged, the red globules sometimes enter, and the eyes are then said to be bloodshot. What is called the *pulse* is the flow of the blood through the arteries, which is caused partly by the impulse of the heart's contractions or beatings, and partly by the contractions of the coats of the arteries. The rate of pulsation in a person in the prime of life is from sixty-five to seventy-five beats in a minute. In childhood, the pulse is much quicker—from 100 to 140 beats; and in old age, it again becomes slower than the medium standard. In fevers, inflammations, and other diseases of excitement, the action of the heart is increased sometimes to from 100 to 140 pulsations in a minute.

Blood-vessels consist of the heart, with its arteries and veins, which branch out through every part of the body, and carry the blood, by a constant circulation, through them. The heart is placed in the left side of the chest, a cavity divided into two parts by a thin membrane running perpendicularly down the centre, and supported below by the diaphragm. It is of a

round or conical shape, with the base or broad part uppermost, and the point slanting downwards and towards the front surface of the chest. It is of a thick muscular substance, with hollow cavities inside, and numerous cords or pillars of fleshy or tendinous substance stretching through these to give them support. In man, and all the higher animals that breathe air through the lungs, it is double, or has two distinct sides, each performing separate offices. In fishes, again, the heart is single; in insects, there is no proper heart, but a vessel that runs along the back, somewhat like an artery, through which the fluid corresponding to blood circulates through their bodies; other animals, still more simple in structure, have no trace of heart or blood-vessels. For these ends, the heart in man has two sides, a right and a left; and each of these sides contains two hollow cavities—the one called an *auricle*, from its fancied resemblance to the ear; the other, a *ventricle*, or belly. The manner in which the circulation of the blood is effected may thus be described in detail:—Two large veins—one from the upper part of the body, the other from the lower—enter the right auricle of the heart, and carry the blood, which has made the round of the body, into this cavity. Here it is of a dark-purple colour, and it is called venous blood, from its coming from the veins. From the right auricle it is sent, by a sudden contraction or forcing together of the two sides of the cavity, into the right ventricle, immediately below the auricle, and communicating with this by a small opening furnished with a valve; by the right ventricle contracting, it is conveyed by the pulmonary arteries into the lungs—the two large cell-formed substances on each side of the chest surrounding the heart. After passing through the lungs, it is returned by the pulmonary veins to the left auricle of the heart; from this it is sent into the adjoining left ventricle; and by a powerful contraction of this muscular cavity, it flows out by the great artery of the heart, the carotid, which distributes it through every part of the body, again to be returned by the veins: and thus the round of circulation is continually going on.

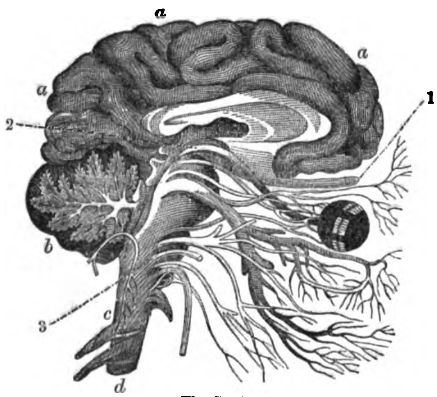
The heart being an extremely thick muscle, the force with which it contracts is very considerable. The left ventricle of the heart, too, although somewhat smaller, is much thicker and more muscular than the right, it having to send the blood through the whole of the body. A beautiful provision is observable in the heart, to prevent the flowing back of the blood into its different cavities during their alternate pulsations. In the passage of communication between the left auricle and ventricle are placed valves, which, when the ventricle contracts, to send the blood through the aorta, close accurately, so as to prevent a reflowing into the auricle. There is the same provision between the right auricle and ventricle, and also at the mouth or commencement of the aorta and pulmonary arteries, and the veins which communicate with the right auricle. Some of these valves are of beautiful structure; they are composed of three flaps that join accurately over each other; and to prevent their being pushed by the impetus of the blood beyond their proper position, they have little tendinous cords attached, of exactly the length required. In the child before birth, as it cannot breathe, and therefore the lungs are not used, there is a small hole or communication between the right and left auricles, by which the blood from the veins flows directly through to the arteries, and thus avoids going to the lungs: this hole is usually closed when the child begins to respire. The aorta, or great artery of the body, after it leaves the heart, passes upward in the form of an arch, when it gives off the carotid branches to supply the brain, and face, and arteries to the arms and chest. It then bends downward, and gives off branches to the stomach and other viscera; and when it comes to the lower part of the belly, it divides into two main parts, which become the arteries of the pelvis, thighs, and legs. The arteries of the body are composed of three coats or coverings, the principal one being a thick muscular ring, which encircles the artery, and which contracts and expands so as to assist in sending the blood onwards. The principal trunks of the arteries lie deep in the fleshy parts of the body; but their ramifications are so numerous and minute, that they pervade every particle of the human structure—bones, gristle, and every other texture. These extreme branches of the arteries are very minute, and previous to the employment of the microscope as an instrument of anatomical investigation, the nature of the connection between the terminal twigs of the arteries and veins was only a matter of conjecture. Now, we know that there is a third set of vessels interposed, called the intermediary or capillary system; they are exceedingly numerous, and anastomose freely with one another, their diameter in the human body seldom exceeding the $\frac{1}{3500}$th part of an inch. In the economy of growth and decay—or that continual building up and pulling down which is always going on in the animal frame—these structures are of the utmost importance, for it is by their means that the great functions of secretion, nutrition, and respiration are mainly brought about. By the aid of the microscope, the circulation of the blood, and other phenomena connected with the above-named functions, can be readily witnessed with the eye—these changes being studied in the transparent parts of animals, such, for example, as the web of a frog's foot, the tail of a fish or tadpole, and the wing of a bat. The veins are another system of vessels, which return the blood from the extremities of the body to the heart. They are larger and more flaccid than the arteries, and are distinguished from them by having no pulsation. A large vein generally accompanies the corresponding artery, but the great proportion of the veins lie more towards the surface, and are easily distinguished, swelling out under the skin. The numerous veins from the lower extremities join into one trunk in the belly, which vein, after passing through the liver, as will be afterwards described, joins the right auricle of the heart, the blood from the upper half of the body joining also by another similar vein. In the veins of the extremities that hang downward, and are apt to be gorged with blood, there are inserted numerous valves at short distances, which prevent reflux of any kind.

THE BRAIN—NERVES AND NERVOUS INFLUENCE.

The brain, as already mentioned, is contained in the cranium. It is a soft mass of matter, enclosed in certain protecting membranes beneath the bones of the skull. As the organ by which mind acts, and chief seat of the nervous energy, the brain may be described as the most important and dignified of man's bodily parts, and well deserves the most careful investigation. The brain is divided by strong membranes into two main sections—the *cerebrum*, or proper brain, which lies in front beneath the brow and on the top and sides of the head; and the *cerebellum*, or lesser brain, which lies behind. Both are longitudinally divided into halves or hemispheres, and also into lesser parts called lobes. The figure in next page offers a lateral representation of the different parts of the brain, as it lies beneath the skull, with its beautiful and minute radiation of nerves proceeding to the eye and other external instruments of the organs of sense.

The cerebrum or principal part of the brain is indicated by the letters *a*, *a*, *a*. The cerebellum, distinguished by the letter *b*, terminates below in the *medulla oblongata*, *c*, the cylindrical pulpy cord by which a union is formed between the brain and *spinal marrow*, *d*. The latter part is the long cord of soft matter formerly mentioned as lying in the canal formed by the range of the spinal bones. It is round, of the thickness of the finger, of the same kind of substance

as the brain, and formed of smaller nervous cords, running parallel to each other: it runs along the whole length of the back down to the pelvis. The



The Brain.

nerves are small whitish-looking cords, which proceed from the brain and spinal marrow, and spread out in innumerable branches to every part of the body. A large branch of a nerve generally accompanies every large artery, and every important part of the body has a branch of a nerve sent off to it. The nerves for supplying the organs of smell (1), of seeing (2), of hearing (3), together with the great sympathetic nerves, which give branches to the heart, lungs, stomach, and other important viscera, proceed directly from the brain. The nerves of motion and sensation, sent to the various parts of the trunk and extremities, take their origin, with a few exceptions, from the spinal cord. Two sets of nervous branches proceed from the cord on each side, corresponding nearly to the junction of every vertebral bone; and it is found that a branch of these nerves imparts motion, and the other sensation or feeling. The brain has a covering of three thin membranes; the outward one strong and thick, the inner, extremely thin and delicate. The nerves, which are soft and pulpy inside, have also a thin external covering which protects them. The nervous branches are never seen or felt in the living body, and what are vulgarly called nerves are the tendons of the muscles, the erroneous title being given chiefly to those about the wrists, fingers, and ankle-joints. Their great numbers and minute divisions are manifest, however, because we cannot prick any part of the body with the sharp point of a needle without wounding some of them, and thereby causing the sensation of pain. When the nerves are injured in their powers by disease, the sense of feeling in the part is entirely lost. The brain in the lower animals is not generally nearly so large, in proportion to their bulk, as in man; and the cerebrum, or upper brain, is often smaller in them than the cerebellum, or lower brain. In several classes of the inferior animals there is no distinct brain, but only nerves running along their bodies, and joining into knots or ganglia. The nervous system of insects and worms is of this description. In the *polypifera*, and many other lowly organised animals, a nervous system cannot be traced.

It may be proper here to make some observations on the functions of the brain, considered abstractly from its anatomy. Man surpasses all other animals in the height and proportions of the forehead, and in the comparative mass of brain in the upper part of the skull. In the human head, the lower parts of the face bear a smaller proportion to the forehead than in the brutes. The face is placed in nearly a perpendicular line with the forehead, instead of projecting outwards into a snout, as in the lower animals. The brute face is merely suited for the purpose of animal wants and for defence; the jaws are long and narrow, supplied with thick, strong muscles, and short teeth; there is not the elevated nose, which in man forms a distinguishing feature—the arched eyebrows—the exquisitely formed lips, and the rounded chin; above all, there is not that play of varied expression, that air of intelligence, and that indescribable emanation of a rational mind, that ray of divinity, at the appearance of which the most wild and ferocious of the brute creation are awed and subdued. But, besides, the Creator seems to have allotted characteristic external signs to express the passions of the mind, that in social life man might not easily impose on his fellow-man; for the various muscles of the face express the several passions of the mind so faithfully, that they may be even represented in painting. This is said to be the natural expression, and would appear to be understood even by animals; for a dog, on looking to the countenance of his master, easily recognises the mute expressions either of commendation or dissatisfaction. From the action of these muscles being so often repeated, *physiognomy* arises: the action of the prevailing muscles fixes an enduring expression on the features; and thus traces of frequent anger often remain in the countenance after the passion itself is gone off. With the power of speech and reason, man has also the means of expressing his feelings and passions by laughter and weeping, manifestations which are not found in the lower animals. Weeping proceeds from a deep emotion of the mind, and seems an effort of nature to relieve the system of grief. It usually begins with deep inspirations of the lungs, after which follow short alternate inspirations and expirations, and it is finished with a deep long-drawn expiration, which is immediately followed by an inspiration. When moderate, it certainly relieves the distress arising from grief. Laughter has its rise from some ludicrous ideas impressed upon the mind, and would seem to arise directly from a sort of titillation conveyed to the branches of certain internal nerves, probably those of the diaphragm; immediately to this succeeds a number of imperfect inspirations and expirations, which seem to be checked by the contraction of the glottis in the throat or larynx. Laughter, in a moderate degree, may be conducive to health, as it gives impulse to, and ultimately promotes, the circulation; carried to excess, however, it may prove dangerous, from accumulating too much blood in the lungs. Sneezing consists of one deep inspiration, succeeded by a powerful single expiration, and seems to consist of a convulsive effort of the muscles of breathing to throw off some cause of irritation in the sensitive membrane of the nostrils. The common hiccup is a spasmodic action of the muscles of the stomach, caused by something irritating the stomach itself. Some of the causes by which our mental happiness is either increased or diminished, proceed entirely from the bodily sensations. Any gentle stimulus applied to a nerve seems to cause a feeling of pleasure; strong stimuli, or any causes disturbing seriously the natural condition, produce pain. Itching is akin to pleasure, and in both cases the flow of blood is increased into the part in which either pleasure or titillation is perceived; but when further increased, it degenerates into pain or excessive sensations in the nerves. Anger violently excites the motion of the spirits, increases the motion of the heart, the frequency of the pulse, and the strength of the muscles; forces the blood into the extreme vessels; and even sometimes bursts the smaller vessels themselves; passion also increases the secretion of bile. Grief weakens the strength of the nerves and action of the heart, retards the pulse, destroys the appetite, and frequently produces paleness, looseness of the bowels, indigestion, and those slow or lingering diseases that take their rise from an interruption of the secreting glands, and a disease of their structure. Fear diminishes the force of the heart, weakens the muscular motions, relaxes the whole system, and, if

long continued, causes a general sinking of the body. Excessive terror often increases for the moment the muscular strength, even to convulsions; excites the pulse, interrupts the course of the blood, and in not a few instances has produced sudden death. Love, hope, and joy promote all the salutary actions of the body, gently quicken the pulse, promote circulation, increase the appetite, and aid the cure of diseases. Excessive and sudden transports of joy, however, often prove fatal, by increasing the motion of the blood, and exciting a fit of apoplexy. Shame, in a peculiar manner, retains the blood in the face, as if the veins were obstructed; when felt in an extreme degree, it has also been known to prove the cause of sudden death.

THE LUNGS OR BREATHING APPARATUS.

In the highest part of the cavity of the chest, on each side of the breast-bone, the lungs are situated. A membrane passing from the breast-bone to the back divides them into two portions—the right lung and the left lung. The right lung consists of three sections, called *lobes*—the upper, middle, and lower; the left lung, rendered smaller in bulk by the presence of the heart in the same cavity, has only an upper and a lower lobe. The lungs have a dark-bluish appearance, a familiar example of which is afforded in the *lights* of sheep—that part generally appended to the heart and windpipe. Inside they are composed of an immense number of cells, which alternately inflate or collapse as the lungs are filled and emptied of air. When an inspiration is made, and the lungs are filled with air, these cells become expanded; and the blood sent from the right side of the heart, and spread over the cells, is exposed through an extremely thin membrane to the air. An important change, as formerly alluded to, here takes place on the blood: from being of a dark-purple colour, it immediately changes to a bright scarlet, having absorbed or taken up all the oxygen, or vital part of the air, and parted with a corresponding volume of carbonic acid gas or fixed air, which it had acquired in its circuit through the vessels of the body. So essential is the matter imparted by the air to the blood for sustaining animal existence, that the breathing cannot be suspended even for a very short period without extinguishing life. It is probable, too, that the heat of the body is generated, and constantly kept up, in some way or other, by means of this process of breathing, and the change which the blood undergoes. We know at least that the evolution of carbonic acid cannot go on, in ordinary chemical processes, without an accompanying discharge of heat; hence it is presumed that the vital warmth, derived by the body from the blood, may be in this way produced. The lungs, like every other internal organ, are covered with a thin transparent membrane called the *pleura:* this membrane, as well as the substance of the lungs themselves, is liable to inflammation; and hence the name of the disease called pleurisy. The *trachea*, or windpipe, the communication between the mouth and lungs, is a hollow tube, having a series of cartilaginous rings passing round it, to prevent the possibility of its being compressed either by external means, or from the food in the act of swallowing, and, in consequence, the breathing obstructed. It takes its rise from the bottom of the mouth, and passes down in front of the neck, where its strong cartilage may be seen and felt. At its lower part, it divides into two branches, one going to join the right section of the lungs, the other the left.

Lungs for the breathing of air are only found in the higher classes of animals. Fishes are furnished with gills, those comb-like substances which lie within a flap on each side of the head; over them a stream of water is constantly sent by inhaling it at the mouth in a similar manner to breathing. The air, which is always present in considerable quantities in water, is thus absorbed by the blood-vessels while ramifying over the gills, and all the purposes of breathing are answered. In insects there are no lungs, nor do they breathe by the mouth, but along the sides of their bodies, by means of numerous holes with small tubes or spiracles, leading to a longer middle tube, by which the air enters and mixes with their fluids. When we descend lower in the animal scale, even this substitute for breathing ceases, the skin or general envelope of the body being sufficiently delicate to bring the circulating fluid in contact with the air, and thereby subserve the respiratory function.

THE TEETH—DIGESTING APPARATUS.

The first process performed in connection with the supply of nourishment to the body is that of masticating the food, and this is the office of the teeth.

The teeth are placed in the upper and lower jaw, to which they are attached by roots, which sink into the porous sockets of the jaw, somewhat in the same manner as a nail is fixed in a piece of wood, though they are retained in their place chiefly by the softer parts around. The teeth are composed of bony matter, covered externally with a thin coat of an extremely hard substance, called *enamel*. The teeth are furnished with nerves and blood-vessels, and have thus vitality like the rest of the body, although possessing it in a less perfect degree than most other parts of the structure. Hence they are very liable to disease and decay. In decaying teeth, a blackish spot is first perceived upon the outer crust or enamel; this substance gradually gives way, and then the bone below proceeds to rapid decay. The irritation of the air, and particles of the food, inflame the nerves and soft pulpy parts inside, and thus the excruciating pain of toothache is produced. The first set, or temporary teeth, begin to make their appearance in the child about the fifth or sixth month; and towards the end of the eighteenth month, the whole set of temporary teeth, consisting of twenty, have generally cut through the gums. These teeth continue till about the sixth or seventh year, from which time, till about the twelfth or thirteenth year, they gradually fall out one by one, and are succeeded by the second or permanent teeth. The roots of the temporary teeth are much smaller, and sink less deep into the jaw than their successors. The rudiments of the second set of teeth begin to form early in cavities below the others, and, gradually growing and pressing upward, displace them. The number of the permanent teeth is thirty-two, consisting of sixteen in each jaw. The four front teeth are called the *incisors*, and have one long root; on each side next to these is one eye or *dog* tooth; then there are placed two small *grinders* on each side, having double roots, and three large grinders, or molar teeth. The last of these is called the wisdom-tooth, from its making its appearance latest in the jaw, from the seventeenth to the twentieth year, or even later. By this change and gradual succession of teeth, we have a beautiful provision of nature for permitting the jaws to increase in size, and at the same time for preserving the relative positions and regularity of the different teeth; for had the first teeth of childhood been permanent, it is impossible that the jaw could have increased in growth without deranging the order and position of the whole.

The teeth of animals differ according to the kind of food on which they live. In the carnivora, or flesh-feeders, the teeth are sharp-pointed, and adapted for tearing their prey to pieces; in the graminivora, or those that live on grasses and other herbage, the teeth are of a rounded form, with broad surfaces, and the grinders are furnished with several layers of the hard enamel, following each other in succession, with a slight layer of common bone interposed; so that when the grinder is worn down by the friction of chewing, it is not rendered useless, but a new layer of the enamel is presented at the worn-down surface. Some animals—as the hare, rabbit, beaver, and mouse—have the front

teeth of a chisel shape, with enamel only on the outer side of them. These animals are called gnawers, because they chew or gnaw down their food in this particular manner; and by the inner soft part of the tooth being liable to be worn down, while the outer is harder, the enamel is thus always kept with a sharp edge. Some animals have large projecting tusks for defence—as the elephant, wild-boar, &c.; others—as fishes—are provided with teeth more for holding fast their prey than for mastication. Many have no proper teeth at all—as birds, worms, and other soft-formed animals. Man is characterised by having all his teeth set close to each other in a half-circle; they are of a medium form, between that of carnivorous and herbivorous animals; the front teeth are adapted for cutting; the canine are sharp, though not of undue length, and the grinders are suited for masticating vegetable and farinaceous matters—as nuts, &c. In short, the form of the teeth of man evidently points out that he is adapted to live on a mixed kind of diet, or a conjunction of vegetable and animal substances.

Stomach.—Behind the windpipe, taking its rise also from the bottom of the mouth, lies the *esophagus*, or tube which passes into the stomach. This tube expands at the top into what is called the *pharynx*, forming the whole of the upper part of the throat immediately behind the tongue. Into this cavity the windpipe opens, and to guard against any particle of the food or drink passing into the windpipe, instead of into the passage to the stomach, there is a little tongue or valve which closes accurately over the mouth of the windpipe every time food or drink is swallowed. When the substances have passed, the valve again springs open, and admits of free breathing. To shew how accurately and precisely every part of the human machine performs its duties, a celebrated writer has instanced this same valve, which, in a multitude of persons dining together, not one time out of a hundred in any one individual instance is at fault. When a drop of fluid or particle of food does by chance insinuate itself into the windpipe, so sensitive is this tube, that a convulsive cough is excited till it is again expelled. There is another little tongue or flap attached to the roof of the palate, and seen above the tongue when the mouth is opened. This, which guards the passage to the nose, is not, however, to be confounded with the other, which is further down the throat, and invisible. The esophagus, or gullet, passes down through the chest, traverses a ring in the diaphragm—that large muscle which stretches across the lower ribs, and which assists so materially in breathing. Immediately below this muscle, on the left side, is situated the stomach, which is partly sustained in its place by being attached to the esophagus, or tube from the mouth. The stomach is an oval bag of considerable size, occupying a slanting position immediately below the heart, with its right side overlapped by the left edge of the liver, and extending to the lower end of the breast-bone. The stomach has three coats—an external membranous one, a muscular, and a soft villous inner covering. The upper passage, by which this bag communicates with the esophagus, is called the *cardiac* opening; the lower, where the first gut commences, is called the *pyloric* orifice.

Digestion.—One of the most important operations in the animal economy is that of digestion, whereby the various substances used for food are dissolved in the stomach, and undergo changes, by which they are formed into matter fit for entering into the composition of the different parts of the body, to nourish its growth, and supply the daily waste which takes place in the system; for such is the constitution of animal bodies, that the substances of which they are composed are liable to constant waste; the solid parts are worn down, and a large quantity of fluid is constantly given off by the exhalent vessels, both from the skin and the surface of the lungs. This is manifest in the sweat and the vapoury exhalations constantly passing off by the mouth; and there is also an imperceptible perspiration regularly proceeding from the surface of the body, which has been computed to amount to several pounds in the course of a day. It must be evident, therefore, that if this waste was allowed to proceed but for a very short period, the body would soon be reduced to a state of complete decay. A constant supply of new material is therefore daily needed, to replace that which is wasted; and thus it has been supposed that a human body changes its whole materials many hundred times from the period of its birth till death; and that an individual, as regards his mere corporeal structure, is not at all the same at the period of manhood to what he was when a boy, nor in old age what he was in his prime. Although this change, then, is complete, even to the bones and most solid parts of the frame, it is brought about so gradually, and with the regular and minute substitution of one particle for another, that it is never perceptible. Man has been called, with relation to his diet, omnivorous, from his being adapted to live on every kind of food, whereas most other animals are confined to one particular description. The carnivorous animals live on flesh alone, the graminivorous on grass and green herbs, and the granivorous on grains and other smaller seeds. These animals never change their respective diets; nor, from the construction of their teeth, stomachs, and intestines, were they ever intended to do so. But in man it is plainly evident, from his anatomical structure, that he was intended to feed on every sort of food promiscuously, or that he could adapt himself to either animal or vegetable fare as habit or necessity impelled him. Man also differs from brutes in resorting to the arts of cooking, whereby the food is put into a state more fitted for digestion, and for yielding a sufficiency of nutritious aliment. The food being received into the mouth, is broken down and masticated by the teeth. It is here also reduced into a soft pulp by the saliva, which flows into the mouth by the salivary glands; and thus being sufficiently broken down and softened, it passes into the stomach. The stomach has numerous glands situated on its inner coat or surface, which secrete a peculiar fluid called the *gastric juice*, which is clear and colourless, with little taste or smell, or sensible qualities. On this fluid depends the important office of digestion. It has the power of coagulating substances in the stomach, of preventing the contents of the stomach from passing into a state of fermentation or putrefaction, and of dissolving the whole into one homogeneous mass. When the stomach is first filled with food, it appears to remain there for a short period without undergoing any change; gradually, however, successive portions of the food, as they come into contact with the gastric fluid, are dissolved; till at length, in a shorter or longer period, the whole is collected into a thin grayish paste, called *chyme*. The chyme, as it is gradually formed, moves to the other extremity of the stomach, called the pyloric, where it passes out to enter the intestinal canal. It would appear also that the pylorus, or lower mouth of the stomach, has a selective or discriminative power, whereby it freely permits the digested chyme to pass out, but refuses exit to the undigested matter. The chyme having passed into the first part of the intestines, or *duodenum*, is then mixed with the bile from the gall-bladder, and with the pancreatic juice. Both these substances, especially the bile, seem essential for the conversion of the chyme into proper alimentary matter; but their peculiar action has not yet been satisfactorily explained. That the liver and bile ducts are of the utmost importance, however, cannot be doubted, from their magnitude, and the care with which they are supplied with numerous vessels, and from their being universally present in a great proportion of animals. The chyme having passed through the duodenum, and having been mixed with the bile and pancreatic juice, now changes its appearance and properties, and becomes

the chyle, or nutritious matter destined to supply the various parts of the system with nourishment. The digested mass is passed gradually along the course of the small intestines, urged forward by what is called their *peristaltic* motion, which is effected by a successive contraction of their fibrous coats. Here the minute terminations of the lacteal vessels absorb the chyle, and carry it, as has already been described, to the receptacle of the chyle, and then by a duct running up the chest along the spine, called the *thoracic duct*, it joins the blood-vessels. The refuse of the aliment which has not been taken up by these lacteal vessels passes on through the large intestines, and at length is ejected from the body. Digestion is not brought about, as has by some been supposed, by any mechanical means, as by the grinding powers of the coats or sides of the stomach, nor by heat alone, nor fermentation, nor by the simple resolution of the food into a fluid; but it is evident that it undergoes a series of chemical actions in the stomach and bowels, whereby its nature and properties are completely changed; and thus animal and vegetable substances, however different, are reduced to one peculiar kind of fluid, the chyle, which, though it may be found to vary slightly according to the kind of food, is, in its general properties, always the same. The gastric juice varies in different animals. In those which feed on vegetable matter, it dissolves these substances only; whereas grain and vegetables pass through the stomach of a purely carnivorous animal without undergoing any change. The gastric juice has this singular property, too, that although it readily dissolves dead animal matters, and reduces them in a short time to a thin pulp, it will not usually act on the living fibre; so that, after death, the coats of the stomach have been found dissolved into holes, by the same juice which, in the living healthy body, had no such effect.

A stomach of some kind or other is found in all the more highly organised animals; for it is by this organ that nutrition and growth are solely promoted. There are some very simply formed animals, whose whole body consists of little more than an oval hollow bag or stomach, with a simple outlet for the mouth to take in nourishment. The common polypi have a mouth and hollow stomach, with several tentacula or arms, by which the creature seizes the worms and shell-fish on which it feeds; these it swallows, the soft parts are digested, and the animal then voids the remainder from its mouth. The common leech has its whole body divided into a number of small cells; and these receive the water, the juices of plants, and sometimes blood, on which it feeds. Flesh-feeding animals have a simple bag for a stomach, and their food is easily and soon digested. Those animals, again, that feed on grass, which is of more difficult digestion, have three and four stomachs, into which the food successively passes after it has been masticated or chewed a second time in the mouth. This is the case with cows, sheep, deer, &c. Birds that feed on grain have first a sap-bag or crop into which the food enters, and remains for a considerable time, mixed with a juice somewhat like saliva: here it is softened and rendered moist, preparatory to its passing into the true stomach, or gizzard, which is an extremely strong muscular bag; in this, with the assistance of a number of sharp-pointed pebbles, which such birds always swallow, it is ground down and acted on by the gastric juice. This compensates for the deficiency of teeth in fowls. Crabs and lobsters have no teeth in their mouths; but in their stomachs will be found three or more teeth, which assist in grinding down the tough sea-weed on which they feed. By domestication, the qualities of the gastric fluid may be so changed, that animals accustomed to live entirely on flesh will exist and thrive on a vegetable diet. This is the case with dogs and many species of birds. All these peculiarities in the natural history of animals illustrate, at least directly, the uses of the digestive organs in the human beings.

THE LIVER, ETC.

The Liver.—Opposite the stomach, on the right side, lies the liver, a large flat substance, of a dark-brown colour, divided into two lobes. The liver has a round, convex upper surface, and is hollow or concave below; it is also thick and solid at the back part, and its edge becomes thinner towards the front, where it lies over a portion of the stomach and bowels. It is suspended in its place by several ligaments attached to the surrounding parts. In the under side of the liver, in a small hollow, is situated the gall-bladder, a small oval bag which contains the *bile*. A tube from this bladder, called the bile-duct, passes into the upper portion of the bowels, carrying the bile there. The liver is supplied by several branches of an artery in the usual way that the other organs are, but it has also a peculiarity which no other organ of the trunk possesses. The large veins, which return the blood from the lower part of the bowels, before going to the heart, enter the substance of the liver, and there spread into innumerable branches throughout its whole surface. From this venous blood the bile is supposed to be secreted, and after having yielded this substance, the vessels collect again into one large trunk, and join the large vein which carries the blood to the heart. The liver weighs, on an average, from three to four pounds' weight; and the quantity of bile which it secretes, taking into account its large supply of blood, must be very considerable. The greater proportion of animal beings are provided with an apparatus of some kind or other for preparing a supply of bile, and in many the liver bears a large proportion to the other contents of the belly. In some animals, as the horse, the gall-bladder is wanting, there being merely a duct to convey the bile into the intestines. In the lowest classes of animals, all traces of liver or gall-ducts disappear.

The Spleen.—This substance is situated below the stomach, on the left side, betwixt it and the ribs. It is in shape a flat oval, and of a dark iron colour. No duct or opening has been discovered proceeding from it, nor has its use been as yet accurately ascertained. Recent researches seem to indicate that its function is that of a blood-preparing gland. It is remarkable that the spleen has been cut out from living dogs, without causing any apparent derangement in the health or digestion of these animals.

The Pancreas.—This substance, known under the name of the sweet-bread, is a large oblong gland (or *secreting* organ), lying across the back part of the belly, extending between the spleen and the middle of the liver. This gland pours out a substance something like the saliva, and by means of a small duct or canal, empties it into the upper bowels, along with the bile from the gall-bladder, both these substances aiding in digestion, and the preparation of the nutritious fluid to be afterwards mentioned.

Lacteal Vessels.—These are innumerably small tubes, proceeding from the ileum, or small intestines, along their whole course, and spreading along the mesentery, where they form an immense number of small knots, or glands, by joining together. These are the vessels which take up the fluid chyle, or milky-like substance, after it has been digested and properly prepared in the stomach and bowels. From these mesenteric glands, the chyle is conveyed by these ducts or canals to another large gland situated in the loins, on the right side of the aorta, and immediately below the diaphragm, called the receptacle of the chyle. From this receptacle the thoracic duct arises, and passing upward by the side of the aorta, or great artery of the body, it joins the left subclavian vein, lying under the left clavicle or collar-bone, and thus pours the whole of the chyle into the general circulation.

The Kidneys.—These are situated in the loins, one on each side of the back-bone, about one-third up the spine. They are in shape somewhat like a French bean,

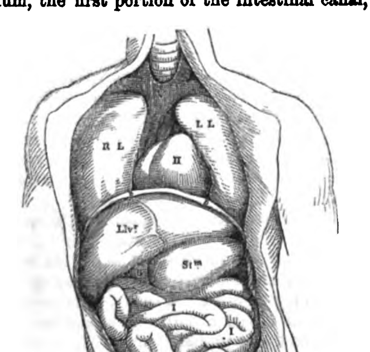
and their internal structure consists of a number of minute porous tubes. They each at the middle hollow part receive a large artery, and their use is to filter from the blood the superabundant fluid, and salts and juices unnecessary for the system, and transmit these by means of two small tubes, called the ureters, to the urinary bladder. These tubes enter the back part of the bladder in a slanting direction, which serves the purpose of valves, preventing a flowing back of the fluid when the bladder is full. The bladder is situated in front, immediately above that bone of the pelvis called the pubis.

The whole cavity of the belly is lined by a thin membrane, called the peritoneum, which is double, being reflected from the sides of the cavity over the whole of the intestinal organs. This peritoneum is liable to inflammation, in the same manner as was mentioned of the pleura, which produces a very violent disease. The coats of the intestines, too, are also subject to the same affection. Dropsy may arise from water being formed between the two folds of the peritoneum.

The Lymphatic Vessels.—These are another distinct set of vessels spread over all the inner cavities of the body, and also throughout the skin. Their office appears to be to take up from the blood a thin lymph, which they convey into the receptacle of the chyle and thoracic duct, and also to absorb moisture from the atmosphere. These vessels are composed of a series of extremely small tubes, and, joining and interweaving, form numerous glands, especially in the groin, armpits, and neck; when swelled by disease, they harden and enlarge, forming knots like a pea or bean. But they are no less numerous on the surface of the inner cavities of the body than on the skin: they are found in the brain, on the surface of the lungs, and in the abdomen or belly. It is a disease or sluggishness of these vessels, whereby they do not perform their necessary duty of taking up all the superabundant fluids, that causes accumulations of water in the chest, belly, and legs. The branches of the lymphatics of the lower half of the body join the receptacle of the chyle; those of the upper part enter the thoracic duct just before the latter pours its contents into the subclavian vein.

THE BOWELS.

From the lower or pyloric orifice of the stomach, the duodenum, the first portion of the intestinal canal, takes



Organs of the Chest and Abdomen.

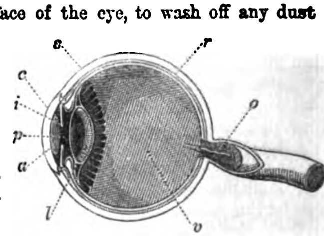
RL, the right lobe of the lungs; LL, the left lobe; H, the heart; V, the great arteries; DD, the diaphragm, a muscle separating the chest from the lower regions; Liv., the liver; Stm., the stomach; G, the duodenum, or beginning of the small intestines; III, the intestines or bowels.

its origin. This gut passes below the liver, and receives the bile-duct, and the duct from the pancreas, when it terminates in the jejunum, which again passes into the ileum, or principal portion of the small intestines. These are of great length, and occupy a great part of the abdomen, being folded and twisted backward and forward in many intricate windings. At the end of the ileum, the colon, a large gut, makes an arch upward towards the right side, and across the belly, and descending at the back part, ends in the short bag called the *cæcum*, which joins the *rectum*, the termination of the intestinal canal. The whole length of the intestines in man is generally about six times that of his average height, or from thirty to thirty-six feet. In all animals that feed on vegetables, the intestines are of great length; whereas in those that derive their nourishment from animal food, they are of much shorter proportions. Two membranous substances, called the *omentum* and *mesentery*, run along nearly the whole length of the intestines, and serve as a means of their attachment and proper suspension in their places. The bowels have three coats—an external one, common to them with the other viscera, a muscular coat, and an internal mucous covering.

THE SENSES.

Man possesses five senses—sight, hearing, smell, taste, and touch—each of which acts through the medium of appropriate instruments, and all regulated by, and acting in connection with, the brain.

Sight—the Eye.—The eye is the exterior instrument of sight, and is a most beautiful and ingeniously constructed object. The eye may be compared in its structure to a telescope, the purpose of both being to collect the rays of light proceeding from the surface of bodies, to concentrate these rays by means of a refracting lens into a focus, and therefore to form a very small image or picture of the object before them. The human eye is placed in a large hollow or socket in the upper bones of the face, surrounded by fatty substance, and the various muscles necessary for moving the eyeball and eyelid. At the upper and outer angle of the eye-socket is placed a gland, which secretes the tears that serve to moisten the delicate surface of the eye, to wash off any dust or other substance, and to keep the ball continually wet and transparent, for the purpose of perfect vision. The tears, after spreading over the eyeball, collect at the inner angle, where, at



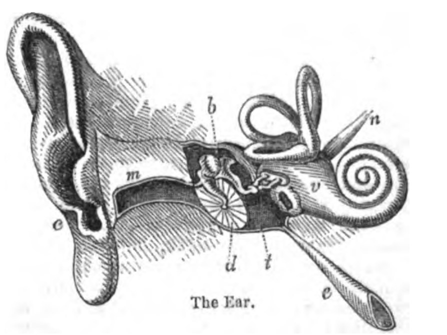
Human Eye Dissected.

each corner of the eyelid, both above and below, there is a small aperture visible, which carries the tears down a passage into the nose. The edges of the eyelids are also supplied with glands, which pour out a mucus that prevents them from adhering together; and these, when irritated and inflamed, are often the seat of disease. The membrane which covers and imparts the white colour to part of the eyeball in front, is called the sclerotic coat (*s*). The middle transparent part of the eye in front is called the cornea (*c*), which is filled with the aqueous humour (*a*) of the eye. Immediately behind the cornea is seen a circular fringed-like substance (*i*), which varies in colour in different individuals, being blue, black, hazel, &c.; hence it is called the iris, or rainbow curtain. This iris has the property of opening and closing, according to the quantity of light which falls upon the eye; and thus the pupil (*p*), a black circle contained within the iris, is enlarged or lessened. Behind the iris is situated the crystalline lens (*l*), in shape resembling the small lens or ground glass of a common telescope, but of unequal swell on each side, being more flattened before than behind. This lens is contained within a capsule, or thin covering of delicate membrane.

A familiar example of the lens of a fish's eye is presented every day in that white globular substance found in such eyes after boiling. The heat coagulates the lens, which is of the same nature as the white of an egg; and in the fish it is nearly a circular body, to adapt the animal's vision to the dense medium of water. The lens is the substance which receives the rays of light entering the eye, and refracts or bends them inwards, whereby they are collected into one point upon the back chamber of the eye or retina, and thus a minute picture of the object seen is formed. If a bullock's eye is taken when fresh, and a hole cut in the skin covering the back part, and then presented to the light with a piece of white paper put opposite the hole, a representation of the objects in front of the eye will be distinctly traced on the paper. When, through disease, the lens becomes of an opaque white colour, and will not transmit the rays of light, the affection is known as *cataract*, producing blindness. The fluid filling the lens is called the crystalline or vitreous humour (*v*). Behind the lens is the back chamber of the eye, filled with a fluid, called, from its thickness, the *crystalline* humour. Over this back chamber the retina (*r*) is spread out like a lining or covering. It is covered over with a black pigment, the better to prevent the intermixture or reflection of the rays of light. On this membrane the optic nerve (*o*), which comes from the front part of the middle brain, and enters the eyeball at the back part, spreads out in numerous branches; and here the small images of the outward objects presented to the eye are painted in miniature. All these objects are painted on the retina in a reversed position, or turned upside down, the same as happens in a common microscope; and how they are perceived in their upright position through the medium of sensation, is a curious question not easily admitting of explanation. Each eye, too, forms a distinct impression of every object; and yet things are not seen double, but both eyes combine to give one impression to the brain or seat of perception. Besides the numerous muscles which roll the eyeball in various directions to adapt it to the various positions of vision, there is also a provision internally by which the crystalline lens is advanced or drawn back, thus adapting itself to the focus of vision in a similar manner as the joints of a telescope are drawn out or pushed inwards. When the cornea is, from its natural form, of too rounded or convex a structure, distant objects are always seen imperfectly, hence causing what is called nigh-sightedness; on the other hand, when it is too flat in form, near objects are then seen indistinctly. This change occurs generally to the cornea as old age approaches; hence spectacles, or artificial rounded lenses, to aid the flatness of the eye, are in such cases made use of with the desired effect. From the different densities of the three humours composing the eye, the refraction or breaking of the light into the various coloured rays is avoided. This, for a long time, was a great objection to telescopes, till different kinds of glass were joined together in the lenses, thus imitating the resources of nature in the eye. The eyes are supplied by two large optic nerves proceeding by separate trunks from the brain; they join together for a short space within the cranium, where they again separate, and each entering an opening at the back part of the orbit, spreads out into branches over the retina. Sometimes these nerves lose their power of sensibility, and total blindness is occasioned without any perceptible disease of the eye; this is called *amaurosis*.

All the higher classes of animals are possessed of evident organs of sight. Birds have in general very acute vision, especially birds of prey, to enable them to distinguish their victims at a great height in the air. They have also a third eyelid, or transparent membrane, which covers the eyeball when they are darting suddenly through the air, and which thus protects the delicate organ of the eye from injury, at the same time that it allows the transmission of a sufficient quantity of light. Fishes have eyes of a somewhat different form from land-animals, to adapt their vision to the denser medium of water, through which the rays of light pass. Insects have great numbers of small eyes or lenses clustered together, like the facets of a gem. Many of the inferior animals—as shell-fish, worms, &c.—have no perceptible organs of vision.

Hearing.—The ear is the instrument of this sense. The outer part or conch (*c*) of the ear is formed so as to collect and transmit the currents of air into the passage (*m*) which leads to the tympanum, or drum (*t*). This passage is defended at its mouth by a number of small hairs growing up in it; there is also a waxy substance constantly secreted, which keeps the whole moist, and is an effectual bar to the entrance of insects or other offensive substances. At the inner end of this winding passage is the thin membrane or drum (*d*), which is stretched out on four small bones (*b*), and which, by its vibrations, conveys through the medium of the nerves the sensations of sound. There are also attached to these small bones several muscles, which,



The Ear.

by their contraction and relaxation, modify the tension of the thin membrane, and prevent sounds from acting too strongly on it, or render it tighter, in order to be even sensible to feeble vibrations. Behind the cavity of the tympanum, or drum, there is another passage which leads from the ear to the mouth, called the *Eustachian tube* (*e*), the object of which is most probably the same as the holes in the common drum—to allow the air to escape from behind, and thus promote the vibration of the membrane of the tympanum; for it is found that if such holes are not made in a drum, little or no sound will be produced; and in the human body, when this tube, leading to the mouth, is choked up by the inflammation of a common cold, deafness is produced. There is another cavity, called the vestibule of the ear (*v*), covered over also by a thin membrane; on this membrane the nerves of hearing are expanded, and convey the sensations of sound to the brain by *n*, the auditory nerve. The sense of hearing is very acute in some animals, especially those that live by prey. In the lower orders of beings, the sense is wanting, but is compensated in a considerable degree by the extreme acuteness of feeling or touch, which is so diffused over their bodies, as to make them sensible of the least agitation in the air by which they are surrounded.

Smell.—The nose is the instrument of smell, and is of comparatively simple structure. The bones forming its inner cavity are of a spongy nature, or rather are composed of a number of very thin plates, covered with a soft membrane, over which the branches of the nerves of smell are minutely exposed. The effluvium proceeding from bodies, indicating their peculiar odour, must pass in a stream or current through the nose before the odour is perceptible. If the air is perfectly still, and no current allowed in the nose, by suspending the breathing through that organ, the strongest smells will make no impression. In some animals the sense

of smell is acute and powerful, beyond the conception of human beings; thus, a dog, by the acuteness of this sense, will distinguish the footsteps of his master amid those of a hundred other people, and can thus trace him for miles, although he has been a long while out of sight; pointers also scent game at a great distance. On the other hand, this sense seems entirely denied to many of the lower animals.

Taste.—The sense of taste is nearly allied to that of smell. The nerves of taste are spread over the upper surface of the tongue, and are raised up in innumerable small points or *papillæ*, like the pile of velvet. Although the tongue is an organ specially adapted to the function of *taste*, this property is by no means exclusively confined to the lingual organ, for the characteristic sensations can also—although in less perfect manner—be perceived by the lining membrane of the palate and back parts of the mouth. That the taste or flavour of many bodies is heightened by the accompanying effects on the organ of smell, is evident; because, if the nose is stopped up so as to prevent the exercise of its functions, many substances having different flavours will taste alike. This is the case with the various kinds of wines, but especially with the ardent spirits. The tongue and whole cavity of the mouth and throat are kept moist by the saliva or spittle, which continually flows into them from repositories placed around the cheeks and under the tongue, called *salivary glands*, which communicate with the mouth by means of small ducts. This saliva flows in greatest quantity during meals, and may even be excited by the sight of food when the appetite is good. It is of essential service in moistening the food, and preparing it for the process of digestion in the stomach. The sensation of taste is in all probability diffused among every class of beings, however low in the scale of existence, although it is probable many animals possess little of it in their mouths, especially when these are formed of hard horny substances, as in many insects, in the lobster, crab, &c., and where any organ corresponding to a tongue is wanting.

Touch.—The sensation of touch is diffused more or less over every part of the body, but is most perfect at the points of the fingers, which in man are generally used to examine the figure and texture of bodies. For this purpose they are furnished with a large supply of very minute blood-vessels and nerves, the latter forming in some situations—according to recent discoveries—peculiar folds within the papillæ of the skin; to these bodies the name of *touch-corpuscle* has been applied. It would appear that there are different nerves that convey the sensation of touch, distinct from those which are the nerves of motion; and that these proceed in pairs from the spinal marrow; and that, moreover, the sensation of heat or cold may be perceived very distinctly in cases where the pricking of a needle or contact of other bodies is never felt. The sense of touch may be said to belong to every animated being, and is one great characteristic of animal life. Vegetables possess a peculiar kind of vitality, and shew what is called irritability of their fibres; but they have no sensation, properly so called. It is probable, however, that sensation is not by any means equally acute in all animals; some feel more intensely than others; and it is a happy provision of nature that it should be so. The lower insects and reptiles, from their structure and habits, are continually exposed to injury; and did they feel it as acutely as the larger animals, the degree of animal suffering throughout nature would be excessive. Many animals bear the loss of limbs with impunity, and some have even the power of restoring these lost members in a very short time. It is probable that according to the perfection of the nervous system, is the acuteness of animal sensation.

On thus reviewing the different parts of the human body, it will be observed that most of its organs are double. On a line being drawn in the middle, on each side will be found parts which are exactly similar to the corresponding side. This is the case with the brain, which is a double organ, having two series of nerves proceeding out from each side of it to go to the respective sides of the body. There are two eyes also, each reflecting a distinct image on the retina; yet the nerves communicate so that only one impression is conveyed to the sense. The arms are double, to suit the various purposes for which they are employed, and so are the lower limbs an essential requisite for the support of the body, and for progressive motion. The lungs, too, may be said to be double, having two distinct lobes; and it sometimes happens that one of them is entirely shrunk or diseased, and yet the important office of respiration is still carried on. The stomach, the liver, and some of the other viscera of the abdomen are, however, single, their several offices being common to the whole body.

THE HAIR AND NAILS.

The hair grows out from the skin somewhat in the manner of a vegetable production. Hairs are fixed by roots in the skin, from whence, by a series of minute vessels, they draw nourishment, and continually increase in length. They possess no sensibility, however, and, unlike the other parts of the frame, may be cut off without producing the least pain. Hair is of different colours in different individuals, being fair in those of light complexion, and deep black in the swarthy. As old age approaches, and even in many young persons, where there is a particular disease in the hair, or dryness in the skin, this colour changes to gray and white. The colouring matter of the hair is principally developed in the centre or medullary portion, and consists of an oily substance, in which carbon, in minute particles, is more or less mingled. The nails are somewhat like hair in their production and composition; they are, like hairs, insensible to the touch, and may be cut or pared without producing pain. They receive nourishment from the blood-vessels of the extremities, and have a constant growth or renewal of their substance. Nails serve as a defence to the tender parts of the fingers; in several classes of animals they form formidable weapons of attack. The horns of cattle are exactly of the same nature as nails, and are chiefly composed of animal gelatine.

The manner in which the various secretions—that are to form hair, nails, wax for the ears, blood, perspiration, &c.—take place in the system, cannot but excite our admiration; for the whole is a chemical process of the most perfect kind, and such as art possesses no power to imitate.

THE SKIN.

An external compact membrane or skin covers the whole body. The outer skin, or cuticle, is unprovided with any blood-vessels or nerves, and consequently is insensible; in this manner it is well suited for a protection to the parts beneath; it is pierced by innumerable minute pores, which are the mouths of the sweat-glands: it is thicker in the palms of the hand and soles of the feet than in any other part of the body. Below the outer skin is a thin membrane called the *rete mucosum*, which, assuming different hues in different nations, gives rise to the variety of colour in the human race. Some have held this membrane to be double, but this is not established. In Europeans, it is white, passing into yellowish brown; in native Americans, of a copper colour; in negroes, of a deep black. The common belief is, that climate has the effect of modifying the colour of the skin, as the black skin only occurs in tropical regions, and it is there found to act as a protection against the scorching influence of the sun's rays. Negroes will remain cool and comfortable exposed to a sun which would be intolerable to a white-skinned person. Their free perspiration seems to be of great service.

Immediately below this net-work is the *cutis*, or true skin, an extremely sensible membrane, so thickly studded with minute blood-vessels and branches of nerves, that the smallest-pointed needle cannot prick it without touching many of them. On the points of the fingers, lips, and other parts of the body, these vessels are very numerous; and hence these parts are endowed with exquisite feelings of touch. Below the skin is situated the cellular membrane, which is a net-work, whose interstices are filled with fat; and it thus serves to fill up the spaces between the muscles, and to make up the shape, and preserve the symmetry, plumpness, and beauty of the whole frame. In cases of emaciation, this fatty matter is sometimes entirely taken up by the absorbent vessels—as after a tedious fever or other lingering disease—when the rough outlines and indentations of the muscles, and the projections of the bones, become painfully apparent.

SLEEP.

The various functions of the body are divided into voluntary and involuntary. When we eat, we perform a voluntary motion; but digestion is performed without the action of the will, or is involuntary. The whole interior functional operations are involuntary, and go on whether we are awake or sleeping.

As a constant supply of food is necessary to repair the waste of the grosser parts of the body, so sleep is essential for the repose and renovation of the finer and more subtile nervous energy. Mere rest alone will not recruit the animal frame; but sleep, or a profound oblivion of feeling and sensation, and every external circumstance, seems essentially necessary at every periodical revolution of the day. Towards the close of a day of exertion, the muscular powers which have been employed in motion, and in sustaining the body erect, begin to suffer particularly: the eyes become dim and heavy, and the eyelids close involuntarily; the lower jaw falls down; the circulation of the blood through the lungs is sluggish, hence frequent yawning is caused; the head nods forwards; all external objects affect us less and less; the thoughts become confused; and at last the profound oblivion of sleep ensues. We are unconscious of the exact moment when we pass into sleep, but occasionally it happens that immediately afterwards we are awaked by a convulsive start, which is caused by the sudden breaking in of the powers of volition, when as yet but newly and imperfectly lulled to rest. Sleep is quite essential to existence. Deprive a person of sleep, and the body sinks under the privation more rapidly than under famine. Indeed, no circumstances, however urgent, will prevent the approaches of sleep for any length of time; and under the severest calamities, and even while in the hour of battle, or when suffering from extreme pain, or cold, or hunger, sleep steals upon us to steep the senses in oblivion. Healthy sleep is so profound, as to resemble, in all that regards self-consciousness, death itself. Sometimes, however, the mind exerts its activity, though it is but a partial exertion; hence dreams, or thoughts of sleep, are made up of all incongruous associations, such as thoughts of the past day and incidents of long bygone years; scenes of actual experience, and others totally imaginary, being all mixed up and jumbled together. In sleep, the heart continues to beat with regularity, and the circulation of the blood is carried on throughout the body; the lungs perform their functions, the stomach digests, and the bowels, and all the glands for secretion, carry on their operations: in short, everything is carried on connected with the sustenance of the body and the existence of the vital powers; but for the most part all other powers, such as those over which we have a control in our waking hours, are at rest. This is not always the case, however, as walking during sleep, or somnambulism, is a peculiarity to which some individuals are liable. Dreams are most common when the sleep is imperfect or too long continued, and thus they occur frequently towards morning, or through the night, if the stomach is loaded and oppressed with food, or the mind harassed and deeply impressed with cares and solicitudes. In a state of health and serenity of spirits, the most profound and most refreshing sleep is during the first period of the night. When asleep, the circulation and breathing are both somewhat slower than when awake, hence the animal heat becomes diminished; and this is the reason why more clothing is required in bed than during the day. This is the reason, too, why a person lying down to sleep out of doors, or on a sofa, with the usual allowance of clothes, feels chill and uncomfortable on awaking. Digestion, too, would appear to go on less vigorously during sleep; and hence the impropriety of going to bed with a full stomach. During the night and darkness, is the most natural and obvious time to select for repose, and it is only the absurd encroachments of fashion that have well-nigh turned day into night. By going early to bed, the damps and colds of night are avoided, which is of essential consequence, especially for the delicate. There is also a natural connection of the functions of the body with the periods of day and night, which makes sleep taken in the first part of the night peculiarly refreshing. The absence of every irritation of the head and other parts of the body—the perfect rest of the mind and external senses—have also great influence in promoting sleep. Again, a variety of causes which weaken and debilitate the body, incline to sleep; such as great losses of blood, cooling medicines, purgatives, coldness of the atmosphere; and narcotics, such as opium and tobacco, drinking largely of wine or spirituous liquors, by first causing great excitement, and afterwards a corresponding debility of the system, also predispose to profound and lethargic sleep. Injuries of the head, by pressing on or otherwise interrupting the functions of the brain, also induce sleep; and great corpulency, by retarding the return of blood through the veins, and thus keeping up a pressure upon the head, is generally accompanied by a disposition to sleepiness.

The period required for sleep by different individuals depends much upon temperament and peculiarities of constitution, as well as on mode of life and habit. While some cannot sleep beyond five, six, or seven hours, others, again, cannot well do with less than eight or nine hours. Children sleep more than half of their time, and require it, and thrive under it; while adults need much less repose. On a general average, eight hours may be reckoned a fair allowance. In order to enjoy grateful and uninterrupted sleep, it is necessary that due exercise shall have been taken during the day; that temperance in food and drink shall have been observed; that strong tea or coffee, which have a stimulating effect on the system, shall not have been taken within an hour or two of going to bed; and that a heavy supper has been avoided. It is true, that gluttony and intoxication produce sometimes deep sleep, but it approaches more to an apoplectic stupor than the calm repose of the temperate.

THE SEXES.

In almost all animals the sexes are distinguished by a difference of form and texture of their bodies; and in many, a superior gloss of colour in the hair or fur, or a superior brilliancy of the plumage, very generally characterises the male of the species. In most animals, too, the males are of superior size, and endowed with greater muscular strength. In the human species, man is marked by a larger and more muscular body than the female; his chest is square and capacious, and particularly at the shoulders, whence it tapers gradually downward; his bones are large, and his joints firm and sinewy; his muscles are round, tense, and conspicuously marked; his limbs thick and fleshy, and his arms powerful; his skin is firm and tense, and his hair strong, crisp, and often curly. The female figure, again, is smaller, less powerful, and in every respect more

delicately formed; the bones are less projecting, the muscles softer, less conspicuous, and more smoothly blended one into the other; the shoulders are narrow and rounded; the greatest breadth of the body being at the pelvis, from whence it gradually tapers upward; the skin is soft and delicate; the hair smooth and of a silken appearance. The mental qualities and dispositions differ somewhat also. Man is commanding, resolute, daring, adventurous, addicted to deep and abstract thought, as well as to high and imaginative speculations. Woman is gentle, submissive, timid: with a mind perhaps little inferior in compass to man, she is more commonly distinguished for acute penetration, nice and delicate discrimination, refined and chastened taste, and elegant and playful fancy. It was the opinion of Plato, that, with regard to the mind, there is no natural difference between the sexes but in point of strength. 'When the entire sexes are compared together,' says he, 'the female is doubtless the inferior; but in individuals, the woman has often the advantage of the man.' With warm and tender attachments, pure morals, and high religious feelings, she is admirably calculated for the sacred charge of watching over and training up the young, and of instilling into their tender and susceptible minds the beautiful lessons of early wisdom—of faith, truth, and charity. All nations, as they have advanced in civilisation, have uniformly increased in that respect and refined attention which is due to the softer sex; and men of the most powerful minds, and of the most splendid endowments, have been the foremost to appreciate those superior qualities which are to be found in a gentle and unsophisticated female.

TEMPERAMENTS.

There are certain conditions of the bodily frame which evidently give rise to varieties of the human constitution, and which have been called temperaments. These have been peculiarly the object of attention to Dr Spurzheim and other phrenological philosophers. As their views on this subject seem to us of a very clear order, a passage is here extracted from one of the journals devoted to that science. 'Dr Spurzheim,' says the journalist, 'recognises four primary or cardinal temperaments, to which he considers all individual cases may be advantageously referred, either as pure, or much more frequently as consisting of two or more combined. I shall first give Dr Spurzheim's brief description of them, and shall afterwards enlarge upon each in detail:

"1. The lymphatic or phlegmatic temperament is indicated by a pale white skin, fair hair, roundness of form, and repletion of the cellular tissue; the flesh is soft, the vital actions are languid, the pulse is feeble, and the whole frame indicates slowness and weakness in the vegetative, affective, and intellectual functions.

"2. The sanguine temperament is proclaimed by a tolerable consistency of flesh, moderate plumpness of parts, light or chestnut hair, blue eyes, great activity of the arterial system, a strong, full, and frequent pulse, and an animated countenance: persons thus constituted are easily affected by external impressions, and possess greater energy than those of the former temperament.

"3. The bilious temperament is characterised by black or dark hair, yellowish or brown skin, black eyes, moderately full but firm muscles, and harshly expressed forms. Those endowed with this constitution have a strongly marked and decided expression of countenance; they manifest great general activity and functional energy.

"4. The external signs of the nervous temperament are fine thin hair, often inclining to curl, delicate health, general emaciation, and smallness of the muscles, rapidity in the muscular actions, vivacity in the sensations. The nervous system of individuals so constituted preponderates extremely, and they exhibit great nervous sensibility."

'The pure lymphatic temperament is characterised by a pallid complexion, soft skin, mostly free from hairs, the hair flaxen, the pulse weak and low; a general tendency to corpulence, and a deficiency of expression in the face. Instances of pure lymphatic temperament are more rare than any of the others, and perhaps are never to be found, except amongst females and habitual invalids, when past middle age, who, from the want of exercise, have lost all trace of some other temperament which they may have possessed in youth. The mental characteristics of the lymphatic temperament are soon told: an insurmountable tendency to indolence, an aversion to exertion of either body or mind, form the hopeful traits. It is therefore obvious that the restraining faculties, Cautiousness and (in some of its manifestations) Secretiveness, are the only organs with the operation of which it will correspond; while all the other propensities, and the intellectual faculties, will be enervated and restrained by it.

'It has been generally supposed that the sanguine constitution is produced by the perfection or redundancy of the circulatory system; and it seems such a natural supposition, that it is difficult for us to allow its proper force to the fact, that individuals of other temperaments are frequently found who can bear loss of blood, by phlebotomy or otherwise, as well as those of sanguine constitutions, and in many instances much better. There is, however, one anatomical peculiarity which appears always to attend the sanguine: the skin is much less disposed to transpiration than the bilious or nervous; and Dr Prichard considers that individuals possessing it are much better calculated to bear cold than others. The Fins, who, as a nation, are decidedly sanguine, bear extraordinary cold winters much better than their more bilious neighbours the Laplanders. Dr Prichard adds, that as the sanguine temperament is very rare in those warmer countries near the spot where man was first placed by his Creator, he considers the sanguine temperament as the result of a natural adaptation to external circumstances, analogous to the white hares and other animals of northern regions; but if this is the case, it is difficult to imagine how the Laplanders should continue tawny, while the Fins, situated further south, are fair. The most striking moral feature of the sanguine temperament appears to be a tendency to enjoyment of the present time, with little inclination to regret the past or to dread the future; and, in general, to look at either past or future no more than is accessory to happiness. The bilious temperament is characterised by a decided cast of features, complexion inclining to brown, dark eyes, and black or dark-brown hair, with the muscles firm and well marked, and the figure in general expressive of vigour, with every motion significant and decided. In combination, it is frequently traced in a slight yellowness of the skin, which can only be detected by comparison, or an extraordinary acute perception of colours; for example, you may frequently find two persons, particularly ladies, the one with dark hair and eyes, the other with flaxen hair and blue eyes. The complexions of both would be denominated fair: on observing them near each other, however, it will be seen that the fairness of the dark-haired one differs considerably from the clear snowy whiteness of the sanguine.

'With respect to the nervous temperament, it manifests itself in a remarkable quickness to learn, and readiness of comprehension, but little tendency to sensual gratification, and an extraordinary power of passing from one subject to another.'

INFANCY—MATURITY.

At the moment of birth, the infant begins to exercise an independent existence, whereas before it formed a part, and was nourished by the vessels of the parent. A general similarity takes place in the embryo growth of most animals, and the familiar instance of the chick in the egg may be taken as an example. The egg is

composed of a centre part or yolk, and of the albumen, or white part surrounding it. In this white part a small darker speck may be seen floating, from whence the first rudiments of the chick are derived. In a few days after the hen has sat on the egg, to impart to it the necessary heat, a small whitish spot will be observed, which is the first rudiments of a brain; in a few days more, vessels will be seen spreading out from a central heart, and forming a net-work all around; gradually an appearance of a head is seen, with indications of brain and spinal marrow; the eyeballs next are formed, then the several parts of the viscera, the projections of the wings and legs; and, lastly, the skin and rudiments of the future feathers. During these periods of incubation the chick has been nourished by the yolk of the egg, which has gradually been absorbed by its vessels for this purpose. At last, when its growth is perfected, and the whole contents of the egg converted into the materials of its body, the little animal begins to pick a hole in the shell, and, by repeated efforts, bursts from its shelly prison, and assumes an independent life.

The infancy of man is of much longer duration, and of a much more helpless nature, than the same state in other animals. A child cannot walk till it is at least twelve months old; and even for a considerable time after that period, it has to be fed and tended with the utmost care; whereas, after a very short time, the young of most animals are able to provide for themselves. A great many, a few minutes after birth, are able to walk about, to search for and distinguish the teat of their mother, and to pick up the food that is suitable for them; and having remained under their maternal protection for a short space, they leave their parents, and never know or distinguish them more. It is very different with the infant: during a long and helpless period of childhood, it is tended by a fond mother, who anticipates all its wants; while it, on the other hand, watches her smiles, and imitates her most minute actions; and thus a reciprocal bond of union is established, by which not only every species of knowledge and experience is acquired for the conduct of after-life, but those moral feelings and sympathies implanted which constitute the great boast and solace of human society.

Man proceeds from infancy to maturity by a slower and more gradual expansion of the bodily structure than any other animal; and this may be one reason of his superior organisation, his greater fitness for supporting labour and fatigue, and the longer period to which his life is extended. From infancy upward the mental powers also gradually expand. This is also different from animals; for in them the faculty of instinct at once is perfected, and never afterwards increases or undergoes any change. In childhood, the mental faculties are constantly active, and on the alert to catch new information, inquisitive to know everything, and imitate every gesture. The facility with which children acquire the knowledge of words, and in a few months master a language, is very astonishing, when we reflect for a moment how much time and pains it takes a grown-up person to become a proficient in any unknown language: and our astonishment will be heightened when we consider that, in the case of children, they have not only to acquire the words and their proper applications, but even to master the articulation of sounds, with all their infinite combinations.

The age of puberty, or that period when boyhood terminates, and manhood commences, varies somewhat in different climates, according to their high or low temperature; the mean period may be reckoned about fourteen years; and between twenty and twenty-five, the growth of the body generally terminates.

About the age of thirty, man may be said to be in his full vigour, with his mental and bodily powers completely developed. Females arrive earlier at a state of maturity than males: in warm climates they are full grown as early as their tenth or twelfth year; in more temperate regions, about their fifteenth or eighteenth year. The proportion of male children born to that of females is as 21 to 20; there is thus a small superabundance of males; but, from various causes, it so happens that there is generally rather a superabundance of females actually existing in society. Among these causes may be mentioned the greater hardships and labours to which men are generally exposed, the devastating effects of war, and, on the whole, the longer life enjoyed by females.

OLD AGE—DECAY.

We have seen that there is within the animal frame a system of operations by which a constant supply of nourishment is afforded to make up for the daily waste and decay, and that every part is constantly undergoing a renewal. To view a man in the full vigour of life, then, we might suppose that, excepting accidents, he was calculated to go on, in the course of existence, for an indefinite period. The principle of life, however, seems to have limits set to its duration, beyond which it fails to keep in healthy motion the animal faculties. The apparatus of life is evidently destined but to last for a certain time. Old age creeps on apace, and the vital flame burns fainter and fainter, till at last it sinks in the socket, and is seen no more. The commencement of decay is perceptible even in youth itself. The child at first grows quickly, from the soft and yielding state of all its vessels; but gradually these begin to thicken and get harder—a greater proportion of earthy matter is adding to the bones. The extremities grow large, while the heart itself does not increase in an equal degree; hence the circulation becomes less and less quick, till the period of full growth. When the growth of the body can proceed no further, a degree of fatness not unfrequently occurs. This proceeds from the superabundant nourishment produced from the food, which, from the impetus or force of the circulation being more lessened by the greater extension and resistance of the body, accumulates in the cellular textures and by the sides of the extreme vessels. In every part of the body the induration produced by approaching age becomes conspicuous—in the bones now wholly brittle, in the skin, in the tendons, in the glands, in the arteries, and in the brain itself, which gets firmer and drier. Moreover, the arteries continue to get denser, narrower, and even shut up in their minute branches. At the same time the nerves become more and more callous and insensible to the impressions of the senses, and the muscles to irritation; thus the contractile force of the heart, and the frequency of its pulsations, are diminished, and, consequently, every force which impels the blood into the ultimate vessels. The quality of humours is diminished in the denser body; the moisture which lubricates the solid parts everywhere manifestly decreases. Nor is the quantity of humours only diminished; they themselves likewise become vitiated. They were mild and bland in children; they are now acrid, salt, and fetid, and loaded with a great quantity of earthy matter. This circumstance of the superabundance of earthy matter is evident in the gouty concretions in the joints of old people, in the frequency of stone, and in the arterial tubes, and even the heart itself, being frequently converted into real bone. The rigidity of the whole body, the decrease of the muscular powers, and the diminution of the juices, constitute old age, which sooner or later comes upon all men—sooner, if subjected to violent labour, or too much addicted to pleasure, or fed upon a too scanty or unwholesome diet; but more slowly, if they have lived quietly and temperately, or if they have removed from a cold to a moderately warm climate.

There are three obvious divisions of human life—a period of youth, including the period before the age of 30; of maturity, from 30 to 50; and of old age, commencing about the period of 50 or 60. The Psalmist

speaks of the age of man being, in his time, only threescore years and ten, or, in rare cases, fourscore years, which may be reckoned the average limit of human existence. After the period of 50 or 60 years, varying of course in different constitutions, the marks of old age begin to make their appearance. The skin becomes more lean and shrivelled; the hair changes to a gray colour, or baldness occurs; the teeth drop out, and in consequence of this, the lower parts of the face, about the mouth and jaws, incline inwards; the muscular motions of the body become less free and elastic—this is especially seen in walking, old people generally treading on the whole base of the feet, and hence having a shuffling gait; the blood circulates slowly; the animal heat is diminished; the pulse occasionally intermits, and the whole energies of the animal frame become lessened; the eyesight begins to fail, and dulness gradually comes over all the senses; the memory undergoes a remarkable change—while recent events pass through the mind and make no impression, the occurrences of early life continually suggest themselves, and are minutely called to remembrance.

Although seventy years is usually the extreme duration of human life, yet a small proportion of those born ever reach even this; a few rare instances occur where 100 years or upward are attained. The famous Parr lived to the age of 159 years; he married at the age of 120; and when 130, was able to thrash, and to do every description of farmers' work. He was at last brought from the pure air and the homely diet of the country into the family of the Earl of Arundel, in London, where he drank wine and lived luxuriously. The sudden change of diet and circumstances, however, proved quickly fatal to him. Henry Jenkins, another poor man, lived to the astonishing age of 169 years, and retained his faculties entire. Some time ago, a statement appeared of the ages of the resident pensioners of Greenwich Hospital, which contained at the time 2410 inmates. Of this number, ninety-six had attained to or passed the age of 80; one only was above 100; fifteen were 90 or more; and eighty were 80 or upward. About forty-two of the ninety-six were of aged families, and in some of this number both parents had been aged. Longevity has in a great number of cases been found to be hereditary. Eighty of the ninety-six had been married; seventy-nine were in the habit of using tobacco in some form or other, and forty-eight had drunk freely; twenty were entirely without teeth; fifty-two had bad, and fourteen good teeth. But the oldest man in the house, who was 102, had four new front teeth within the five preceding years. The sight was impaired in about one-half, and hearing only in about a fifth part of the number.

Old people are not generally inclined for much exercise, nor is it suited to their stiff joints and impaired vigour; for the same reason, they cannot endure much cold. Cheerful company, especially the company of the young, is peculiarly grateful to old people. Innocent amusements and recreations are also of great consequence, and the mind should be exercised in some useful or amusing pursuit. Cities, or, at all events, constant and agreeable society, are favourable to the condition of old age. In lonely secluded country-places, the mind sinks prematurely into a total gloom and blank, for want of sufficient stimulus and variety to keep up the vigour of thought and play of ideas. Few deaths occur from what is commonly called old age, or a gradual and simultaneous decay of all the functions. It may be said to happen when the powers gradually decay, first of the voluntary muscles, then of the vital muscles, and, lastly, of the heart itself; so that in an advanced age, life ceases through mere weakness rather than through the oppression of any disease. The heart becomes unable to propel the blood to the extreme parts of the body; the pulse and heat desert the feet and hands, yet the blood continues to be sent from the heart into those arteries nearest to it, and to be carried back from them. Most commonly, however, some one part gives way, and disease gradually coming on, cuts off the lingering flame of existence. Thus the body, after having grown up to maturity, and flourished in its prime, sinks to the earth, and moulders into the elements of which its several parts are composed.

CONCLUSION.

The admirable structure of the body of the human being, and its superiority in every respect to that of the lower animals, afford a most perfect proof of design in the all-wise Creator, and is one of the most striking instances of the impossibility of our formation being the result of blind chance. Paley, after going over a great number of examples of this kind of design in a Creator, proceeds to state that, in all 'instances wherein the mind feels itself in danger of being confounded by variety, it is sure to rest upon a few strong points, or perhaps upon a single instance. Amongst a multitude of proofs, it is *one* that does the business. If we observe in any argument,' he continues, 'that hardly two minds fix upon the same instance, the diversity of choice shews the strength of the argument, because it shews the number and competition of the examples. There is no subject in which the tendency to dwell upon select or single topics is so usual, because there is no subject of which, in its full extent, the latitude is so great, as that of natural history applied to the proof of an intelligent Creator. Perhaps the most remarkable instances of mechanism in the human frame are the pivot upon which the head turns, the ligament within the socket of the hip-joint, the pulley or trochlear muscles of the eye, the epiglottis, the bandages which tie down the tendons of the wrist and instep, the slit or perforated muscles at the hands and feet, the knitting of the intestines to the mesentery, the course of the chyle into the blood, and the constitution of the sexes as extended throughout the whole of the animal creation. To these instances the reader's memory will go back, as they are severally set forth in their places: there is not one of the number which I do not think decisive; not one which is not strictly mechanical; nor have I read or heard of any solution of these appearances which in the smallest degree shakes the conclusion that we build upon them.

'The works of nature require only to be contemplated. When contemplated, they must ever astonish by their greatness; for, of the vast scale of operation through which our discoveries carry us, at one end we see an intelligent Power arranging planetary systems, and at the other concerting and providing an appropriate mechanism for the clasping and reclasping of the filaments of the feather of the humming-bird. We have proof not only of both these works proceeding from an intelligent agent, but of their proceeding from the same agent; for, in the first place, we can trace an identity of plan, a connection of system, from Saturn to our own globe; and when arrived upon our globe, we can, in the second place, pursue the connection through all the organised, especially the animated, bodies which it supports. We can observe marks of a common relation, as well to one another as to the elements of which their habitation is composed. Therefore one mind hath planned, or at least hath prescribed, a general plan for all these productions. One Being has been concerned in all.'

ZOOLOGY.

ZOOLOGY—a term composed of the Greek ζῶον, an animal, and λόγος, a discourse—aims at classifying animals according to their outward characters and habits.

By outward characters are meant those peculiarities of structure which most conspicuously distinguish animals. Judging by these characters, we can see that some are greatly inferior to others—made, as it were, upon a simpler pattern: for example, worms are simpler than insects, and therefore inferior to them; so, likewise, are fishes simpler than and inferior to poultry and cattle. Hence arises a *gradation* amongst animals, though not of a kind as yet thoroughly ascertained or understood. We can see, however, one clear *principle* in the ranking of animals; namely, that where there are many repetitions of one organ or feature—as, for instance, in the feet of the centipede, or the rays of the feather-star—it is a mark of inferiority, while it is equally true that the concentration of any branch of organisation is a mark of elevation in the scale. We can also trace *analogy* among certain groups of animals, shewing them to be, as it were, comparatively near relations to each other. On gradation and affinity are based all attempts to classify animals.

The first and most important term employed by the zoologist is *species*, as applicable to a certain form and certain characters which remain permanent in successive generations. Thus, the sheep is a species. The honey-bee, also, is a species. The zoologist aims at giving each species of animals a name by which it may be distinguished.

To a number of species having kindred characters, he applies the term *genus*—meaning a kind. A number of genera, again, with more general characters of resemblance, are usually grouped as an *order*. For example, the Ruminant Animals—cattle, deer, &c.—form an order. Sometimes, however, a group of genera, having certain traits in common, is called a *family*; for example, the crow, jay, black-bird, &c., form the family *Corvidæ*. In these instances, a group of families constitutes an order. A *class*, again, is a combination of orders; for instance, Birds are a class. Thus, we come to very general characters; but there are some still more general, according to which we divide the entire Animal Kingdom into four *sub-kingdoms* or *provinces*. Thus we have Provinces, Classes, Orders, Families, Genera, and Species—each term, in succession, being applicable in a more and more particular way than its predecessor. Nor is *species* the last and most particular term, for in many species there are *varieties*. These, however, are regarded as only the transient effect of the conditions in which the species may live.

The four Provinces of the Animal Kingdom are:—1. Radiata, or Rayed Animals. 2. Mollusca, or Pulpy Animals. 3. Articulata, or Jointed Animals. 4. Vertebrata, or Backboned Animals. It is according to these four principal forms that all animals appear to have been modelled—the subordinate divisions being merely slight modifications, founded on the development or addition of certain parts which produce no essential change on the plan itself.

PROVINCE FIRST.

RADIATA.

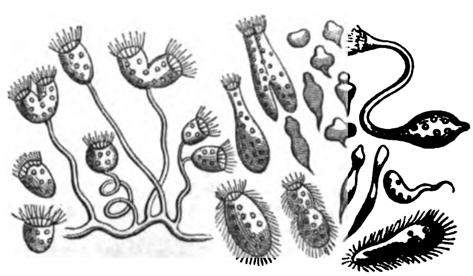
This sub-kingdom was so named by Cuvier, because many of the animals included in it are more or less radiated in plan; that is, exhibit rays or branches. Of all animals, they exhibit the lowest degree of organisation. They are wholly confined to a watery medium or sphere of existence. On account of the obscure form which the nervous system takes in them, some naturalists have proposed for them the name *A'crita* [ἄκριτος, undiscernible]. A number of them, apparently hovering in character between plants and animals, or externally resembling plants, are called Zoophytes (*plant-animals*).

The *Radiata* are divided into five classes—Infusoria, Phytozoa, Acalephæ, Entozoa, and Echinodermata.

CLASS INFUSORIA.

The INFUSORIA are microscopic animalcules; that is, animals so small that they cannot be seen without the aid of the microscope. In all stagnant water, or in any water in which vegetable or animal matter has been infused and allowed to decay, these minute animals are found, being, it is supposed, developed from germs conveyed thither by obscure means. Besides the orders here enumerated, there is a large family of objects, called *Diatomaceæ*, which are not yet with certainty referred to the Animal Kingdom. They consist of single cells, in cases of silex or flint, of numberless forms, found living and moving in all water which has been exposed to the air, and dead in the mud of rivers, in guano, and in many alluvial deposits.

ORDER POLYGASTRICA are the most minute of the ascertained infusory animals. While some species are naked, others are clothed in silicious cases; and it has so happened in the history of the world, that thick strata have been composed of the hard exuviæ of these humble creatures. Though individually invisible to the naked eye, these animals, by their immense numbers, impart a distinct colour to the water in which they swarm, and



Various forms of Animalcules.

they are one of the causes of the phosphorescence of the sea. The order includes two families—*Urcularia* and *Cercarea*.

ORDER ROTIFERA.—These have a gelatinous body, of an oval shape, with a mouth and a stomach. About the head there is a very singular organ, variously divided into tubes with toothed edges, which vibrate in various ways, and when viewed under the microscope have the appearance of one or more toothed wheels revolving with greater or less rapidity. This organ, from which the order derives its name, is supposed to be in some way connected with the function of respiration. The Rotifera are so exceedingly minute, that a drop of water is to them as a lake in which they may disport themselves.

CLASS PHYTOZOA.

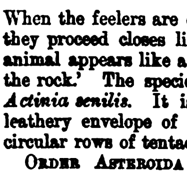
The PHYTOZOA are so named from their external resemblance to plants: they are otherwise called Zoophytes (Animal Plants) and Polypifera. The general

character is that of a small animal or polype, consisting of a stomach, and a mouth surrounded by tentacula (organs for holding).

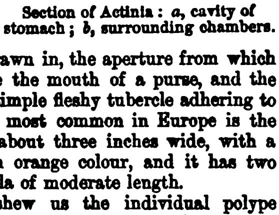
ORDER HYDROIDA have for their fundamental type the *hydra*, a simple polype, usually seen enjoying an independent existence, attached by a stalk to some twig or other object, in stagnant water. The hydra seldom exceeds an inch in length, but is sometimes as long as six inches. The body is wholly gelatinous, consisting only of a kind of bag, which serves as a stomach, with a circle of long arms or tentacula round the mouth. 'Small larvæ, worms, and entomostracous insects seem to be their favourite food; and to entrap these, they expand their tentacula to the utmost, and spread them in every direction, moving them gently in the water to increase their chances. No sooner is their prey laid hold upon, than it evinces every symptom of painful suffering; but its violent contortions are momentary, and a certain death suddenly follows its capture. How this effect is produced, is mere matter of conjecture, as not even a wound can be perceived on the dead animal.'

Hydra.

ORDER HELIANTHOIDA—so named from their resemblance to the popular pictures of the sun and his rays—consists of a variety of fleshy polypes, which have the power of fixing themselves by the base, though many of them also crawl, and allow themselves to be moved along by the current of the water. The family *Actiniidæ* (ἀκτίς, ray, and εἶδος, form) have the body of a soft gelatinous texture, and often brilliantly coloured. Their tentacula are arranged in several rows around the mouth, having the appearance of full-blown many-petaled flowers, whence they are called sea-anemones and sea-sunflowers. They are among the most highly organised of the class, and feed on shell-fish and other marine animals, which they draw into the mouth with their tentacula, disgorging shortly afterwards the shells and other indigestible parts. 'They are very sensitive to light, and expand or close their tentacula according to the fineness of the day.



Actinia seen from above.

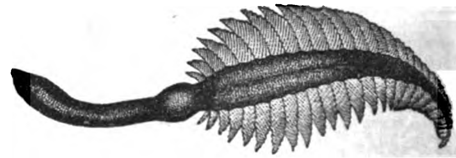


Section of Actinia: *a*, cavity of stomach; *b*, surrounding chambers.

When the feelers are drawn in, the aperture from which they proceed closes like the mouth of a purse, and the animal appears like a simple fleshy tubercle adhering to the rock.' The species most common in Europe is the *Actinia senilis*. It is about three inches wide, with a leathery envelope of an orange colour, and it has two circular rows of tentacula of moderate length.

ORDER ASTEROIDA shew us the individual polype sinking, as it were, under the compound form. One noted family, *Alcyonidæ*, are of a spongy character. They are well known on our coasts under the name *dead-men's-fingers*, and others, referring to their flabby character and the forms they present. What seems a disgusting fleshy mass in the fisherman's net, proves to be, when placed at ease in its proper element, a structure of wonderful beauty. The mass is traversed by a multitude of minute canals, terminating in prominences, from which the polypes protrude.

In the *Pennatula*, or Sea-pen, we see the asteroid



Pennatula.

zoophyte acquiring solid parts. It has a stony axis, flexible at the extremity, and from which a regular series of lateral branches passes off on each side, like the barbs of a feather, each bearing a polype. This genus has a special interest for the geologist, as one of the earliest of fossils, the *graptolite*, evidently belongs to it.

ORDER ASCIDOIDA—called also Bryozoa—comprehends several families and many genera; but it may be sufficient in this place to advert only to a noted species—the *Bowerbankia*. From a sort of creeping stem arise separate polypes, each enclosed in a horny transparent sheath, with ten long and slender tentacula surrounding the mouth. The œsophagus or gullet terminates in a cavity analogous to a gizzard, having thick muscular walls, lined with tooth-like processes. Below this is the true stomach, from which a tube ascends to an outlet near the mouth. The whole economy of this animal, its feeding and lively movements, form a most interesting microscopic study for the naturalist. It has latterly been concluded that the Bryozoa, though bearing a general resemblance to polypes, are entitled to a higher place in the scale of creation. Under the names Foramenifera, Linulites, &c., their microscopic shells are found in enormous abundance in chalk and limestone.

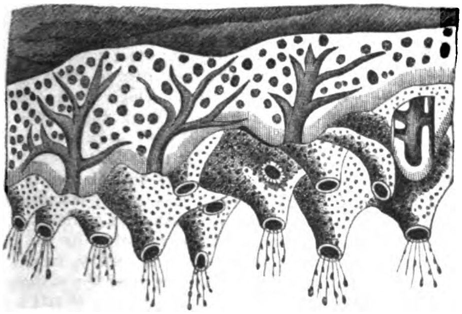
Bowerbankia: *a*, œsophagus; *b*, gizzard; *c*, stomach; *d*, orifice of intestine.

ORDER PORIFERA might be generally described as compound polypes, the individuals being connected by a membrane extended over an internal massive structure, calcareous or horny in its character. In one large family this internal structure is the substance called *coral;* in others, it is that no less familiarly known as *sponge*. The material of coral is secreted and deposited by these animals, and the hugeness of the masses which it forms in some oceans is one of the most wonderful facts in natural history. Extensive reefs and considerable islands in the South Sea are composed of coral, the product of these minute polypes; and the formation named Mountain Limestone is believed to have originated in the same manner.

On carefully examining the Sponge, it is seen to contain a number of minute orifices or pores, extending in channels through the substance. In a living state, when enveloped in membrane, the only vital action that can be traced is a continual passage of water into and out of these channels, being probably for the purpose of supplying the animal with nourishment. In some species, the vents are at the extremities of small protuberances, so that the issue of the water is somewhat like the eruption of a number of volcanoes, but in a downward direction.

In this humble department of creation, the animals are reproduced, not merely by *ova* or germs prepared within the body of the parent, but in various other ways. 'Reproduction by buds [*gemmiparous reproduction*] occurs among the polypes and some of the infusoria. On the stalk, or even on the body of the Hydra, and of

many infusoria, there are formed buds, like those of plants. On close examination, they are found to contain



External surface and sectional view of Living Sponge.

young animals, at first very imperfectly formed, and communicating at the base with the parent body, from which they derive their nourishment. By degrees, the animal is developed; in most cases, the tube by which it is attached to the parent withers away—the animal is detached, and becomes independent. Others remain through life attached to the parent-stalk, and in this respect present a more striking analogy to the buds of plants.

'Reproduction by division, or *fissiparous reproduction*, is still more extraordinary. A cleft or fissure at some part of the body takes place, very slight at first, but constantly increasing in depth, so as to become a deep furrow; at the same time, the organs are divided, and become double; and thus two individuals are formed of one—so similar to each other, that it is impossible to say which is the parent and which the offspring. The division takes place sometimes vertically, and sometimes crosswise. In some infusoria, this division occurs as often as three or four times in a day.'—Agassiz. As already implied, these modes of reproduction are only additional to the universal mode by germs or *ova*.

CLASS ACALEPHÆ.

Acalephæ (ἀκαλήφη, a nettle) are so called from the property many of them possess of irritating and inflaming the skin, the cause of this property being still undiscovered. Cuvier divided the Acalephæ into two Orders, marked by the possession or non-possession of an air-bag to sustain them in the water, calling the former *Hydrostatic* and the latter *Simple*. More recent inquirers arrange them in four groups, named from peculiarities of structure, *Pulmonigrada*, *Ciliograda*, *Cirrhigrada*, and *Physograda*. The most important forms are the *Medusa*, or common jelly-fish, the *Beröe*, and the *Physalia*.

Medusa.—The body of this creature is in the form of a gelatinous disk, more or less convex on the upper surface, somewhat like the head of a mushroom, and termed the umbrella. From the centre of this, and from the margin, there depend in most of the species tentacula, more or less numerous, and elongated. When the Medusa is seen dead on the beach, it appears as a piece of coarse jelly, and it is difficult then to imagine the lively and beautiful movements of the living animal. The solid parts of the Medusa form so small a proportion of its frame, that if a specimen of ten pounds' weight be filtered, the residue will weigh but two drachms! Yet though they are so very soft, they feed upon prey of firm structure—such as crustacea, and other marine animals of much higher organisation than themselves, which, being probably overcome by their stinging power, are quickly seized and dissolved in their stomachs. Many of the species of medusæ are phosphorescent, and when disturbed, shine in the gloom of night like globes of fire.

Beröe.—The species of this family have globular bodies provided with salient bands, extending from the centre of the upper surface to that of the under, and bristled with cilia or filaments, by which their motion through the water is effected. One species, the *B. pileus*, which is understood to constitute a great portion of the food of the common whale, is frequently seen in the English Channel. It has the appearance of a bright globe of jelly, about half an inch in diameter.

Physalia.—The animals of this family have an oblique and wrinkled salient crest on the upper surface, and are furnished below, near one of the ends, with a number of cylindrical appendages. They float upon the surface of the sea when smooth, and the crest answers the purpose of a sail. They are commonly called Portuguese men-of-war, and are often seen in hundreds floating along with the Gulf Stream and other currents of the ocean.

Physalia.

CLASS ENTOZOA.

The Entozoa (ἐντός, within, and ζῶον, an animal) are almost all parasitical on the intestinal organs of other animals. Many of them infest various parts of the human body—as the intestinal tube, the bronchial glands, the kidneys, and the voluntary muscles; and the injury they occasion, when their numbers become excessive, is well known. The habits of intestinal worms are as obscure as their habitations; and the purpose they answer in the economy of nature is quite a mystery. They have colourless blood, circulated in the higher species in a closed system of vessels, without an auricle or a ventricle. They have no visible respiratory organs, no articulated members for locomotion, and no organs of sense. This class admits of subdivision into two Orders—*Nematoidea*, Round-worms, having the intestine floating in a distinct abdominal cavity; and *Parenchymata*, with viscera obscure.

Order Nematoidea (νῆμα, a thread, and εἶδος, form), or Rounded Worms, consist of only one family—the Thread-worms (*Filaridæ*). They are so called on account of the body being long, slender, and threadlike. They are found imbedded between the coats of the viscera, and in similar situations. They are not confined to the larger animals, but are found also in insects and their larvæ, as well as in various mollusks.

The species of thread-worm most dreaded by man is the Guinea-worm (*Filaria medinensis*), which insinuates itself under the skin, generally of the leg, and frequently causes great agony and convulsions. It is about equal in size to a pigeon's quill, and is peculiar to hot countries. The genera of thread-worms, besides the *Filaria* proper, are *Tricocephalus*, *Ascaris*, *Strongylus*, and *Lernea*.

The Order Parenchymata have cavities for the reception of food, carved out, as it were, of the soft, almost homogeneous, tissues of their bodies. Some of them are of eel-like form; such are the so-called *eels* in vinegar, and certain little parasites found in the muscles of man. To this group also belongs the *Tænia* or tapeworm, a creature composed of an indefinite series of parts, all connected by one alimentary canal, but having reproductive organs on each part, and which has been known to reach many yards in length. A head, with four mouths, surrounded by a double circle of small hooks, enables the animal to attach itself to a nourishing surface; and should all the parts except a small number be broken off from the head, new ones will be formed, and the individual animal will continue to live.

One of the most simple of all the entozoa is the *hydatid* or *acephalocyst* (headless bag), a mere sac or stomach with a mouth, which infests the liver and other organs of various animals, including the human species.

The young hydatids grow in the interior of the parent, which perishes when they come to maturity. Allied to this animal is the *distoma* or *fluke*, which infests the liver of sheep, and gives rise to severe disorders. The *Planaria* is a similar parasite, but residing in the water, where it attacks the surface of various animals. In the forepart of its body are two specks, believed to be eyes; a sucker, or mouth, is in the centre; and the reproductive apparatus is behind. Each of these parts, when separated, speedily becomes a complete animal.

CLASS ECHINODERMATA.

Echinodermata (ἐχῖνος, urchin, and δέρμα, a skin), or Spiny-skinned Animals, are so called because they have a crustaceous or coriaceous covering, generally armed with tubercles or spines like that of the hedgehog. They are all marine, and in their adult state move freely about. There are two Orders: those with feet or vesicular appendages, answering the same purpose; and those without them. These are respectively termed *Pedicellata* and *Apoda*.

Order Pedicellata (*pedicellus*, diminutive of *pes*, foot) consist of three well-defined families—Star-fishes, Sea-urchins, and Sea-slugs.

The family of Star-fishes, *Asteriadæ* (ἄστρον, a star), are so called because the body is generally in the form of a star, with rays springing from a central disk, in the middle of the lower side of which the mouth is situated. The framework of the body is composed of horny plates, variously arranged. Through each orifice, the animal can protrude a tubular organ, capable of adhering to the surface of any body. These enable them to draw prey towards their mouth, and are also subservient to the purpose of locomotion. Professor Rymer Jones says: 'If the common star-fish of our coast, which, when it is left by the retiring waves, appears so incapable of movement, be placed in a large glass jar filled with its native element, hundreds of feet will gradually protrude, and fix themselves to the sides of the vessel as the animal begins to march.' They feed upon almost any organised substance, living or dead, that falls in their way.

The family of Sea-urchins or Sea-eggs (*Echinidæ*) have the body covered with a crust of calcareous matter, in segments nicely adapted to each other, and perforated by regular rows of holes for the membranous feet; and the mouth, as in the star-fish, is generally directed downwards. Their food is of a mixed character, consisting of crustacea and sea-weed. The most common of the sea-urchins, properly so called, is the *Echinus esculentus*. This species, which is found in all European seas, equal in size to an ordinary apple, is closely set with short spines, and is generally of a violet colour.

The family of Sea-slugs (*Holothuridæ*) have an oblong body, resembling a cucumber, with a leather-like covering open at both ends. In tropical seas they are very numerous, and many of them are splendidly coloured. Some of the species are edible, and, when dried, are the trepang of commerce. By the Malays they are diligently sought after, for the supply of the China market.

Order Apoda resemble the Holothuridæ in form, but want the feet (ἄπους, without feet); and their leather-like skin is quite unarmed. In their movements they resemble worms; some are found under stones, while others burrow in the sand.

PROVINCE SECOND.

MOLLUSCA.

The term *Mollusca* (from *mollis*, soft) was applied by Cuvier to a large department of the Animal Kingdom, composed of animals having no skeleton, internal or external, but possessing soft bodies, usually enclosed for protection in a shell. The muscles are simply attached to various parts of the skin, and by alternate contractions and expansions of that covering, enable the animals to creep, climb, swim, burrow, and seize upon various objects, according as the form of their parts may permit. Mollusks, however, are generally sluggish in their movements.

The greater number of Mollusks are constant inhabitants of the sea; many, however, live in fresh water, and some dwell upon the land. Their blood is pale, and never truly red. Nearly all of them have an extensive fold of the skin reflected over their body, which it covers like a mantle. It is sometimes extended into a breathing-pipe, or branched and divided in the form of fins. When the covering is simply membranous or fleshy, or when a horny or testaceous rudiment of a shell is developed, but remains concealed in the substance of the mantle, the mollusk is said to be *naked*. When the shell is so much enlarged that the contracted animal finds shelter beneath it, the species is said to be *testaceous*.

The nervous system of the Mollusca is unsymmetrical, being composed of a ring enclosing the gullet, and connected with ganglia or nervous masses in other parts of the body.

Some of the Mollusca are exceedingly small; so much so, that they will pass through holes pricked in paper with a needle. Others are of large bulk; the Tridacna or Clamp-shell, for instance, reaching the weight of 500 pounds. Some of them are of humble organisation, verging on the character of the radiated tribes; others, again, possessing the rudiment of a skeleton, are considered as making an approach to the Vertebrata. The shell is a membrane, composed of minute cells, in which is deposited calcareous matter, the whole being secreted from certain portions of the organisation of the animal. It is either in one piece, or in two, giving rise to one leading term of classification—namely, *univalves* and *bivalves*. The bivalve mollusks are the humbler of the two divisions; from being deficient in a head, they are comprehensively termed Acephala (ἀκέφαλος, headless, from α, privative, κεφαλή, the head).

The formation of the shell is a curious process, depending entirely on the mantle. The margin of this integument is provided with glands, and sometimes also with a fringe of minute tentacula. The animal extending the border of its mantle to the border of the shell, deposits there a fresh layer of cells, containing calcareous matter; thus, layer after layer, it extends its living mansion, in just proportion to its own growth. The border of the mantle contains, in some species, patches of colouring matter, secreted in glands, and the shell becomes variously coloured accordingly. Ridges and spines projecting from the general outline of the shell, are produced by corresponding expansions of the mantle. After the coloured exterior deposit has been formed, the animal thickens it by an interior lining, formed of matter secreted from a different portion of the mantle, and nacreous (mother-of-pearl) in its character. Should any particle of sand have intruded, or any predaceous enemy attempt to bore through the shell, the deposition of nacreous matter is increased at that spot, till a globular prominence is formed, presenting beautiful iridescent colours. Such is the history of the formation of those *pearls* which have long been so highly prized by all nations.

The Mollusca are divided by Agassiz into three Classes—*Acephala*, *Gasteropoda*, and *Cephalopoda*.

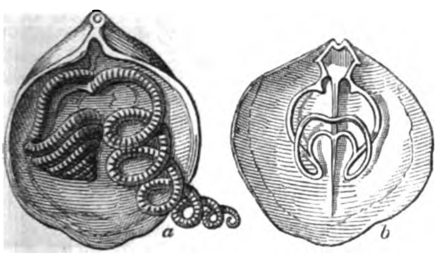
CLASS ACEPHALA.

Order Tunicata.—These are characterised by having the body covered with an elastic cartilaginous tunic, which appears to serve in place of a shell. They are very humble animals, often found associated in strings and clusters, generally unattractive in form, but in some instances transparent and beautiful. One family, the *Ascidians*, has been a favourite subject of study with naturalists. They possess a gill-sac, in which the sea-water is driven about for purposes of respiration, while

the minute particles of food which it contains are at the same time propelled into the stomach. Another curious peculiarity is in the circulation; for after the blood has been sent out for a time by one set of vessels, and received back by another, the process is reversed; and so on alternately.

Among the *Salpæ*, a family of the Tunicata, was first observed the singular phenomenon called *alternate reproduction*. These humble animals, while floating in long chains in the sea, produce each an egg, from which comes a creature, different in form from the parent, and living solitarily. This little animal, in its turn, propagates by a kind of budding, which gives rise to chains seen within the body of the parent, and these again bring forth solitary individuals. Thus each animal resembles, not its parent, but its grandparent.

Order Brachiopoda (Arm-footed) are so called because of their possessing two long ciliated arms, supposed to be used for creating currents, by which food may be brought to the mouth. The valves of their shell are not connected by a hinge, as in the higher acephalans, but by means of certain muscles of the animal's body, by which they are brought together like the boards of a book. The Brachiopoda are dwellers in deep water, are widely diffused over the earth, and make a conspicuous appearance in the earliest fossiliferous strata. The genera *Lingula* and *Terebratula* are fixed by means of a fleshy footstalk to submarine bodies. In *Orbicula*, the pedicle is wanting, and the lower valve of the shell



Terebratula:
a, valve with the spiral arms; *b*, valve with arms removed.

becomes itself the means by which the attachment of the animal to the rock is effected.

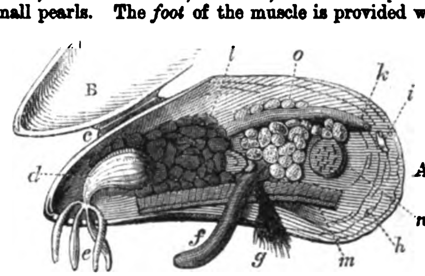
Order Lamellibranchiata (Plate-shaped Gills), or *Testaceæ;* also named *Conchifera:* the latter two names referring to the shells by which they are covered. In this order are included the great mass of bivalves familiar to common observation—as the oysters, muscles, cockles, &c. The most conspicuous peculiarity is the *branchiæ*, or breathing-apparatus, forming a double fringe to each lobe of the mantle, and neatly arranged within the margin of the shell. Another is the *adductor muscle*, by which the animal can draw the valves of its shell close together when it apprehends danger. The shell of a conchifer, unlike that of the brachiopod, has a hinge, which often remains in good condition long after the death or removal of the animal; in some instances, it is made stronger by having *teeth* which lock into each other. In many of the conchifera, there is also a fleshy muscular organ called the *foot*, passing out between the edges of the mantle, and serviceable as a limited means of locomotion.

The Oyster family (*Ostreadæ*).—The edible oyster, *Ostrea Edulis*, has, as the late Professor Forbes remarked, its capital in Britain; for, though found elsewhere on the coasts of Europe, nowhere does it attain such perfection as in our seas. The oyster is deficient in a foot, and is fixed to the sea-bottom by the shell alone. It employs its branchiæ, and the minute cilia with which these are covered, in making currents in the water for the purpose of bringing animalcules to its mouth, which is situated near the hinge, under a kind of hood formed by the edges of the mantle.

In the month of May, the oysters cast their spawn, which the dredgers call the *spat*. It clings to stones, old oyster-shells, and pieces of wood, at the bottom of the sea. It is conjectured that the spat in twenty-four hours begin to have a shell. The oyster is considered full grown for the market when from four to seven years old. Until the third or fourth year, each annual growth is easily observed; but after their maturity, it is difficult to count the layers. Aged oysters become very thick in the shell.

The *Pecten*, so called from the resemblance of the shell to a certain kind of comb, forms the type of a family intimately connected with the oyster, but of higher organisation, being provided with a well-developed foot, and having eye-specks.

The Muscle family (*Mytilaceæ*) are well represented by the common muscle (*Mytilus Edulis*), which is found in great abundance on our shores, usually near the mouths of rivers. Some species are inhabitants of fresh water; and one of these, the *Unio*, is noted for producing small pearls. The *foot* of the muscle is provided with a



Interior of Muscle:
A, right valve; B, left valve; *c*, hinge; *d*, stomach; *e*, tentacula; *f*, foot; *g*, byssus; *h*, branchial orifice; *i*, vent; *k*, termination of intestine; *l*, liver; *m*, gills; *n*, adductor muscle; *o*, ovarium.

collection of hair-like filaments (the *byssus*), by which it attaches itself to solid objects. This curious arrangement, and the other principal parts of the organisation of the muscle, are depicted in the prefixed engraving. Belonging to this family are some remarkable boring mollusks, which have the power of penetrating hard rocks, and making deep holes, which are enlarged as they advance, in accordance with the growth of the animals, and which, therefore, they cannot quit. No mechanical means for producing this effect is observable, and it may be conjectured that the process is of a chemical character.

The Clam, or Spiny Oyster family (*Spondylidæ*), are inhabitants of the Mediterranean and the warmer seas, and are found at various depths attached to coral rocks and dead shells. Their shells, the upper valve of which is armed with spines, are often tinged with lively colours. Several splendid species exist within the tropics.

The Cockle family, *Cardiaceæ* (*cardium*, a cockle), are of numerous species, and the shells of many of them are very beautiful. Cockles are enabled by a large development of the foot to burrow in the sand of the sea-shore.

The *Myadæ* are remarkable for their power of boring and burrowing, so as to form for themselves a habitat. The razor-shell (*solen*) can thus sink a way for itself into the sand with surprising rapidity. Some species of the genus *pholas* are equally noted for their power of boring into wood. Fixing themselves by the foot, they cause their shell to revolve, and thus with its edge cut a way in, the wearing of the instrument being constantly replaced by a fresh formation. They thus serve a useful purpose in destroying waste timber floating in the ocean; but when they attack ships, or wooden sea-works, the mischief done is incalculable.

CLASS GASTEROPODA.

This is an extensive class of mollusks, and perhaps the most typical of their province, since they have its general characteristics, of a well-developed nutritive

system and sluggishness of habits, in the highest perfection. They derive their name Gasteropoda (γαστήρ, the belly, πούς, a foot) from their organ of locomotion, which is a muscular disk projecting from the abdomen, and capable of progression by alternate dilatations and contractions.

Cuvier has arranged the Gasteropoda in nine orders, according to their organs of respiration.

ORDER CYCLOBRANCHIATA (κύκλος, a circle, and βράγχια, gills).—In these gasteropods the gills consist of little tufts or pyramids, attached in a circular arrangement to the inner surface of the margin of the mantle.

The Limpet family (*Patellidæ*).—Among these we find the power of locomotion at its lowest ebb, for they seldom move far from the spot on which they were produced, and many of them, from the shape of the shell corresponding to the surface of the rock, appear never to have left it. The Common Limpet (*Patella Vulgaris*) is universally distributed around our coasts. It subsists on sea-weeds of different kinds, and lives on the surface of rocks and stones between tide-marks. It is sometimes used for food, though much too tough to become a delicacy.

The Chiton family, *Chitonidæ* (χιτών, a garment), are characterised by a series of testaceous symmetrical plates, implanted in the back part of the mantle. Guilding says, these animals live on rocks and stones of the sea-coast, and are distributed nearly over the whole globe. Many species are constantly under water, while others ascend above high-water mark, spending the day exposed to the hottest sun, or resting on spots occasionally moistened by the rude and restless surf. They seem to feed entirely by night. Though they remain stationary during the day, yet when disturbed they will often creep away with a slow and equal pace; sometimes sliding sideways, and creeping under rocks and stones for concealment. If accidentally reversed, they soon recover their position by violent contortions and undulations. They sometimes roll themselves up for defence.

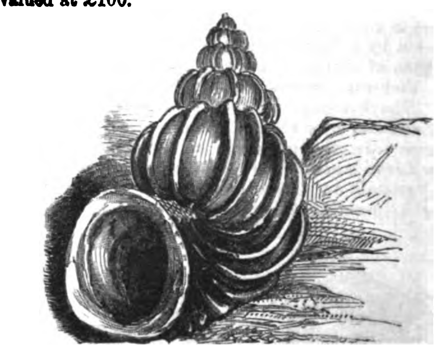
ORDER SCUTIBRANCHIATA (*scutum*, a shield, and *branchiæ*, gills) derive their name from having the gills covered with a shell in the form of a shield. The Ear-shell family, of which *Haliotes* is the type, are furnished with a handsome ear-shaped shell. They are inhabitants of the sea-shore, and live near and under rocks and stones. Their range is south of Britain as far as the Canaries. They are cooked for food; but a more important use of them is in making those mother-of-pearl ornaments which constitute so much of the beauty of works in papier-mâché. Great quantities of Haliotes are brought to Birmingham for this purpose.

ORDER TUBULIBRANCHIATA (*tubulus*, a small tube, and *branchiæ*, gills) are so called from having long tubular snake-like shells, more or less irregular, in which the branchiæ or gills are lodged. These animals are permanently attached to other bodies, and have no power of shifting their station.

ORDER PECTINIBRANCHIATA (*pecten*, a comb, and *branchiæ*, gills).—This is the most extensive order of the class, since it includes almost all the spiral univalve shells, as well as several which are merely conical. The order is thus characterised by Cuvier: the branchiæ, composed of numerous leaflets or fringes, ranged parallel, like the teeth of a comb, are affixed in two or three lines, according to the genera, to the floor of the respiratory cavity which occupies the last whorl of the shell, and which communicates outwards by a wide aperture between the margin of the mantle and the body. They have two feelers, and two eyes, raised sometimes on pedicles, with a mouth in the form of a proboscis, more or less lengthened. Under this order—the species of which are mostly carnivorous—are placed eight Families.

The Trochus family, *Trochidæ* (τροχός, a whorl or top), are so called from the pyramidal shape of their shell, which resembles a top. The whorl for the body is flattened, and the aperture is closed by a horny operculum, or lid. The species are all marine. Some of our most elegant British univalves, and many of the most ornamental exotic shells, belong to this family. They are remarkable for boring into the shells of other mollusks. The buckie is perhaps the best known example.

The Marine Snail family (*Turbinidæ*) are characterised by having a shell of a regular turbinated form, generally much elongated, and a mouth entirely circular. With respect to their habits, it would appear that they frequent submarine banks covered with sea-weed, and are all vegetable feeders. A few are natives of fresh waters, and a limited number respire air. They are found in great abundance in the Indian seas, and are used as food, many being of large size. The winkle is a form of the family with which all are familiar. Another genus, the *Scalaria*, is remarkable for the beautiful and striking form of its shell, one example of which has been valued at £100.



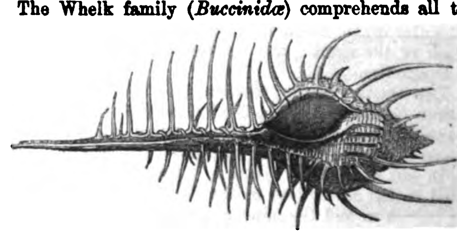
Scalaria Preciosa, or Wentletrap.

The family *Capuloidæ* have a shell with an expanded opening, and but slightly turbinated, without operculum, notch, or a siphon. They do not appear to remove from the spot to which they are first attached, a cavity more or less deep being formed in the surface to which they adhere, either by the chemical agency of some solvent fluid, or by the long-continued operation of currents of water.

The Volute family, *Volutidæ* (*voluta*, a spiral wreath), form an extensive and interesting group, having beautiful shells, but all of them decidedly carnivorous. In the majority, the eyes are sessile, being placed at the extremities of two short tentacula; and the mouth is of a trunk form, and extensile; while the foot in the typical species is of enormous size. They are almost confined to warm latitudes.

The Cowry family (*Cypræidæ*).—From the polish of their surface, and the beauty of their markings, the shells of the Cowries are in considerable request as mantel-piece ornaments, and have been in demand in most countries from time immemorial. The shell of one species of Cowry, *C. Moneta*, is commonly used by the natives of certain parts of Africa, and other semi-barbarous regions, as money. It is yellow, or white with a yellow ring, the margin and base being tubicular.

The Whelk family (*Buccinidæ*) comprehends all the shells which have no fold at the columella or lip, but a notch or a short inflected canal towards the left. The



Murex Tenuispina.

mollusk is of a spiral form, with the foot shorter than the shell. The head is furnished with two tentacles, and the mouth with a proboscis. The common whelk abounds everywhere on our coasts.

The Spindle Shell family, *Muricidæ* (*murex*, the purple-fish), have a univalve spiral shell, with a small oval aperture, ending in a straight or slightly ascending canal. The splendid shell of the *M. Regius*, which is found along the western shores of South America, is one of the ornaments of the cabinet of the conchologist. The Muricidæ, together with the Buccinidæ, appear to be destined to keep in check the superfluous numbers of the bivalve mollusks and herbivorous gasteropods, by drilling their shells and draining their juices.

In the *Strombidæ*, the aperture of the shell is much dilated; the lips expanding, and extended into a groove leaning to the left. The Strombidæ are carnivorous in their habits, and are tenants of the seas of hot latitudes. The number of the species is considerable, and many attain enormous dimensions. In several of them, pearls have occasionally been discovered.

The *Conidæ* form an extra genus or family, comprising many species, one of which, the common *Cone*, possesses a shell of uncommon elegance of form, and rendered additionally attractive by fine colouring.

Order Heteropoda (ἕτερος, different, other, and πούς, a foot).—This order comprehends those gasteropods which have the foot compressed, and in the form of a thin vertical fin. The branchiæ, which are plum-like, are situated on the hinder part of the back, directed forwards; and immediately behind them are situated the heart, liver, and viscera.

The genus *Carinariæ* (*carina*, a keel) are characterised by having the heart, the liver, and the gills protruding from the body, and incased in an extremely fragile and beautiful shell, the convexity of which is terminated by a single keel, whilst the tail is furnished with a sort of fin, which performs the part of a rudder.

The genus *Firoles* in general resemble the Carinariæ; but no shell has been observed. Their snout is prolonged into a recurved proboscis. They are common in the seas of the warm or temperate latitudes.

Order Tectibranchiata (*tectus*, concealed, and *branchiæ*, gills) comprehends those species in which the gills are folliculated on the right side or on the back. These animals are generally covered by a small bubble-shaped shell, concealed in the folds of the mantle. They are all marine, living chiefly on the shore, or on floating sea-weed. They may be further described as thick, fleshy, soft mollusks, generally possessing a distinct head, furnished with a pair of ear-shaped tentacula, and with the mantle usually dilated into two lobes resembling fins, with which they can both

Bursatella Leachii.

swim and crawl. Many of the species are very large, and when taken out of the water appear like great oval masses of flesh. This order consists of two Families. The *Bullidæ* (*bulla*, a bubble) have the shell so perfect as sometimes to be capable of receiving the greater part of the animal, and it is always more or less convolute. The *Aplysianidæ* possess a mere rudimentary shell, resembling one-half of a bivalve. The upper tentacula probably suggested the idea of the ears of the hare; whence the common name of sea-hares given to these animals by the fishermen in most countries.

Order Inferobranchiata (*inferus*, lower, and *branchiæ*, gills) have the gills situated beneath the extended margin of the mantle, and consisting of two long series of leaf-shaped organs. They are incapable of swimming, and are confined to the shore. Their food consists of sea-weed. This order in the system of Cuvier comprehends only two families—*Phyllidia* and *Diphilidia*—of which little is known.

Order Nudibranchiata (*nudus*, naked, and *branchiæ*, gills).—This order of gasteropods, which might be denominated sea-slugs, have the gills exposed on some part of the back, in the form of a rosette, so as exactly to resemble a bunch of vine leaves whose stalks form a common centre. It includes all the naked marine gasteropods, as Triton, Doris, and Tethys. They are generally ornamented with beautiful colours. Besides moving about like other gasteropods by means of their foot, or concave under side, in the depths of the ocean, some species—as the Tritons and Dories—have the power of swimming and crawling on the surface of the sea, with the foot uppermost. In swimming, they are propelled both by their branchiæ and the sides of their body, which act in the manner of fins.

Order Pulmonata (*pulmo*, a lung) Snails and Slugs, the most advanced of gasteropods, are furnished, instead of branchiæ, with a vascular net-work of pulmonary vessels, fitting them to breathe the atmospheric air. Most of them, accordingly, are land-animals; and those which are aquatic—living chiefly in fresh waters and brackish pools—are obliged, like the whales and seals, to come occasionally to the surface to breathe. All the breathing gasteropods feed chiefly on vegetables, and many of them exclusively so; but some are extremely voracious, and will devour almost any organised matter that falls in their way. They are diffused through all climates, particular species being restricted to each.

The aquatic pulmonata have only two tentacula. The family *Lymnæidæ* (Pool Snails) reside in stagnant waters, feeding upon plants and seeds, and having, for the digestion of the latter kind of food, a very muscular gizzard. Another noted family—*Planorbis* (Marsh Snails)—are distinguished by having the coil of their shells upon one plane. They are very common in England.

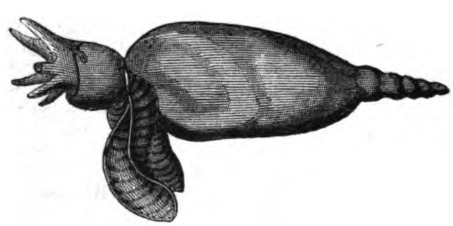
The *Lymnæa* is remarkable from its connection with a very curious phenomenon in the reproduction of entozoa, lately brought to light. The *Cercaria* is a small parasitic animal, a little like a tadpole in form, which, by means of a sucker, attaches itself to the body of the Lymnæa, on which it lives. By and by, while in this condition, it is transformed into a kind of worm, with a double sucker, and is recognised as the *Distoma*. We thus become aware that the cercaria is a transient or immature form of the distoma, as the caterpillar is of the insect. The question arises—What is the origin of the cercaria? It appears that, at a certain season of the year, the viscera of the Lymnæa contain a quantity of little worms, of elongated form, with a well-marked head, and in each of which are clearly to be observed a number of young cercariæ. When these have reached a certain size, they leave the body of the worm, and escape also from that of the Lymnæa, to fasten upon its exterior, there to pass on to the subsequent condition of the distoma. Naturalists call the worm the *nurse* of the cercaria. They further observe these nurses to be the produce of another intestinal worm in the Lymnæa, one longer and more slender, and to which they give

the name of the *grand-nurse*. Supposing these grand-nurses to be the immediate progeny of the distoma, as is probable, we have thus a quadruple series of generations, each presenting an animal more or less peculiar in its form.

The family of *Helicinæ* (Land Snails) are among the most familiarly known of all animals. They possess a shell, generally much thinner than that of the marine gasteropods, and into which they withdraw themselves under apprehension of danger or when at rest. They feed exclusively on vegetables, biting off pieces of the leaves by means of a horny plate attached to the upper lip; and their destructiveness in gardens is well known. The common Garden Snail of this country (*Helix Hortensis*) is much exceeded in bulk by the Great Vine Snail (*H. Pomatia*) of France and Italy, which has also been occasionally found in Britain. More striking examples of the family are to be found in tropical climates, where some species of the genus *Bulimus* attain to so great a size, that their eggs are as large as a pigeon's. In some species, the direction of the coils of the shell is opposite to what it is in other spiral shells; such are said to be *reversed*. Another large snail of tropical climates is the *Achatina*, which feeds on trees and shrubs, and is generally distinguished by the beautiful colours of its shell.

The family of *Limacinæ* (Slugs) are naked or unshelled snails, noted as the pests of gardens on account of their great destructiveness amongst vegetables. The slug has a prominent head, with four tentacula, and at the end of the longer pair the eyes are situated. These tentacula (usually called the *horns*) can be drawn in by a process resembling the inversion of the finger of a glove. On the back there is a kind of shield or disk, which sometimes encloses a small shell, and under which is placed the pulmonary sac or breathing-apparatus.

PTEROPODA are a remarkable group of marine mollusca, which Agassiz places in connection with the Gasteropoda. They are small animals, generally destitute of shells, and provided with wing-like appendages, by which they move through the water; hence their name (πτερόν, a wing; and πούς, a foot). The body is symmetrical, and hence the better adapted for swimming. The Pteropods are found in enormous multitudes; one of them, the *Clio Borealis*, which abounds both in the



Clio Borealis.

Arctic and Antarctic Seas, forms a very important article of food to the whale, which swallows thousands at a mouthful. This little animal is itself eminently carnivorous, and well fitted to seize the minute animals which form its prey. Its six tentacula are provided each with about 3000 invisible filaments, each of which is furnished with about twenty *suckers;* thus each clio is computed to possess 360,000 examples of that form of pneumatic apparatus, for the purpose of prehension or seizing—a complexity of structure considered as perhaps without parallel in the animal creation. When the prey is drawn to the mouth, it is there reduced by a series of sharp thorny teeth, set like those of a comb upon a pair of horny jaws; and it is then drawn into the gullet by the tongue, which is covered with regular rows of spiny hooklets, all directed backwards, and evidently intended to assist in the act of swallowing.

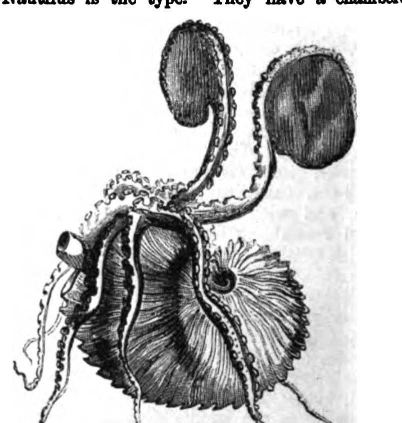
CLASS CEPHALOPODA.

The Cephalopoda are so named from their having their limbs arranged in immediate connection with the head. These limbs, in some eight, in others ten in number, perform all the offices of feet, arms, and feelers, and in many genera are used also as fins. The head, from the arrangement of the limbs, is in the centre, like that of the Radiata. They are, nevertheless, the most highly organised of invertebrate animals, presenting rudiments of an internal skeleton, developed for the purpose of protecting a brain and lodging organs of sight, and, in most of the existing species, organs of hearing. They possess distinct hearts, for the systemic and pulmonary circulations, and highly complicated digestive, secretory, and respiratory organs. The head is large and conspicuous. All the species are marine and carnivorous.

ORDER DIBRANCHIATA (δὶς, twofold, and βράγχια, gills). This order includes those species which have two gills, and are characterised by having three distinct hearts, an apparatus for secreting and emitting an inky fluid, and cephalic arms, never above ten in number, solid, and supporting suckers.

The most typical form of this order is the Cuttle-fish, *Sepiadæ* (σηπία, a cuttle-fish). These animals have immense arms, which are also used as legs; by these they crawl with the greatest facility on the bottom of the sea, swim quickly in the water, and retain a forcible hold of the animals upon which they prey. Their eyes are large, and fully developed, like those of the vertebrated animals. In size, cuttle-fish far exceed all the testaceous mollusks, and may be termed the giants of the Invertebrata. The common species forms the bait with which one-half of the cod-fish is taken off Newfoundland. All the varieties of the Sepiæ yield a dark-coloured juice; and the typical species, *S. Officionalis*, is chiefly sought after for the profusion of fluid which it affords.

ORDER TETRABRANCHIATA (four-gilled) consists of only one family, *Nautilidæ* (ναῦς, a ship), of which the genus Nautilus is the type. They have a chambered



Nautilus.

cell, with simple septa, or divisions, perforated in the centre, concave towards the outlet of the shell, and with the last chamber the largest, and containing the body of the animal.

PROVINCE THIRD.

ARTICULATA.

The *Articulata* (*articulus*, small joint), or Jointed Animals, rank much on a general level with the Mollusca; but being allowed to have a superiority in the nobler

parts of the animal structure, they may be arranged as third, instead of second, in the ascending scale.

They are characterised by having their bodies in segments, and by the greater number of them possessing an external skeleton or case, adapted to the segments of their bodies, and to which muscles are attached. While the vegetative portion of the frame—namely, the organs of nutrition and circulation—are more largely developed in the Mollusca, the organs of the animal powers, the nervous apparatus, and arrangements for locomotion, are more largely seen in the Articulata. They have a symmetrical double nervous cord extending along the whole body, studded with knots or *ganglia*, from which proceed branches to the various segments, and terminating anteriorly in a kind of brain, in the form of a ring surrounding the gullet. The Articulata are consequently distinguished by comparative activity of movement, one large class—the Insects—possessing generally a power of rapid flight in the air. This department of the Animal Kingdom is also noted for the immense variety of its forms, some of its orders presenting many thousands of distinct species.

Professor Agassiz considers the Articulata as capable of being arranged in three Classes—namely, Worms (*Annellata*), Crustaceans, and Insects. The Arachnida, (Spiders), however, which Agassiz would class with Insects, are usually placed separately.

CLASS ANNELLATA.

This is decidedly the lowest form of Articulata. The body consists of a long series of segments, without any hard casing, and without any limbs. They are divided into three Orders, distinguished by their respiratory organs.

ORDER ABRANCHIA (α, priv., and βράγχια, gills), are so called because they have none of the ordinary external organs of respiration, but breathe from the surface of the skin, or, as some suppose, by interior cavities. The greatest part of the animals of this order live at the bottom of the sea, or in fresh water; but a few—like the earthworm—reside in humid ground. The order is divided into two Families—*Lumbricinidæ* (Worms) and *Hirudinidæ* (Leeches).

The Worm family, comprehending the aquatic genus Naiades, and the Earthworms, are remarkable as provided with silky bristles. The common earthworms are of marked importance to the agriculturist, by pulverising the soil, and rendering it more fit to receive the fine fibres of roots and shrubs.

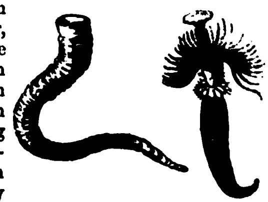
The Leech family (*Hirudinidæ*) have an oblong body; both ends are adapted to fix on bodies by a kind of sucker, by means of which these animals move when out of the water. When in their native element, they swim with facility. Its mouth contains three rows, each armed with a double range of very fine sharp-set teeth, which enable it to pierce the skin without inflicting a dangerous wound. In summer they retire into deep water, and are taken by nets made of twigs and rushes. Leeches are very common in the south of France.

ORDER DORSIBRANCHIATA (*dorsum*, the back, and *branchiæ*, gills) have their gills or breathing organs projecting from the middle parts of the back or sides of the body, where they assume the form of little ramified branches, tufts, plates, or tubercles. The greater number of the species of this order live in the mud, or freely swim in the ocean; but a few, like the next order, inhabit tubes. One of the most interesting families of this order is the *Nereidæ*, or Sea-centipedes, many specimens of which occur on our own coasts. Some of the Nereids exhibit a singular peculiarity in their mode of propagation. The hinder part of the body, being gradually transformed into an additional animal, is cast off by spontaneous division.

A species of the Dorsibranchiates which inhabits the sand (*Lumbricus Marinus*) is very abundant on our coasts, and is dug up for bait by fishermen. It is nearly a foot in length, of a reddish colour, and ejects, when touched, a quantity of yellow fluid. It has three pair of gills.

ORDER TUBICOLÆ (*tubus*, a tube, and *colo*, I inhabit) are so called because they generally occupy tubular sheaths, consisting either of calcareous matter, secreted from their own bodies, or of particles of clay, or of very fine gravel, agglutinated together to serve as a habitation.

The most common Tubicules on our coast are those which belong to the genus *Serpula*. They are found incrusting the surface of stones and shells which have been dredged up from the bottom of the sea. Professor Jones remarks: 'If, while the contained animals are alive, they be placed in a vessel of sea-water, few spectacles are more pleasing than that which they exhibit. The mouth of the tube is first seen to open by the raising of an exquisitely constructed door, and then the creature cautiously protrudes the anterior part of its body, spreading out at the same time two gorgeous fan-like expansions of a rich scarlet or purple colour, which float elegantly in the surrounding water, and serve as branchial or breathing organs.'



Serpula Contortuplicata, taken out of its tube.

Closely allied to the Annellata are the MYRIAPODA or Centipedes, and the IULIDÆ, of which the common Gallyworm is the type.

CLASS CRUSTACEA.

The Crustacea, so called from the hard calcareous case in which they are enveloped, are characterised by a branchial respiration and a dorsal ventricle or heart. From comparative inertness, and large development of the feeding-system, they resemble the Mollusca more than do any of the other articulate classes. They are chiefly marine, and of carnivorous habits. As in insects, the body comprises a head, thorax, and abdomen, which, however, are in some combined in one piece. In the head are compound eyes, a mouth with *mandibles*, frequently furnished with *palpi* or feeling organs, and *maxillæ* in some instances prolonged into a pair of feet. From the thorax proceed four pair of true legs, and one pair of claws, which sometimes reach a large size. The abdomen is also in some families furnished with feet, giving the animal a resemblance to the myriapod. As the investing shell does not increase with their growth, they throw it off periodically, even to the hard facets on the exterior of the eyes, and thereafter a new shell grows upon the soft surface. Cuvier divides this class into two great sections—the MALACOSTRACA (μαλακός, soft, and ὄστρακον, a shell, the term soft being applied in a comparative sense), including all the true calcareous-shelled animals of the class; and ENTOMOSTRACA (ἔντομος, incised), embracing those which have the integuments of the body of slender consistence, and corneous or horny rather than calcareous.

The *Malacostraca* are divided into five Orders.

ORDER DECAPODA (δέκα, ten, and πούς, a foot), a name applied by Cuvier to this order, because they have ten thoracic feet. Most of the species are useful as food.

The family of *Brachyura* (βραχύς, short, and οὐρά, a tail), or Crabs, have the tail or post-abdomen short and folded beneath the trunk. The Edible Crab (*Cancer pagurus*) is the type. In summer, at low tide, they are found in holes of rocks in pairs, male and female; and if the male be taken away, another will be found in the hole at the next recess of tide. By knowing this fact, an experienced fisherman may twice a day take with little work a vast number, after having discovered their haunts. In the winter, they are supposed to

burrow in the sand, or to retire to the deeper part of the ocean.

Crab.

The Land Crabs—called also Violet Crabs and White Crabs, from their colour—are natives of the West Indian Islands and South America. The history of these creatures presents some singular phenomena, from the circumstance of their living in mountainous districts away from sea and water, and inhabiting burrows and holes in trees. During the period of their migration to the sea for the purpose of depositing their eggs, they cover the land in vast multitudes, and spread destruction wherever they go. Their journeys are usually performed during the night.

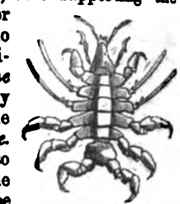
The family of *Macrura* (μακρος, long, and οὐρά, a tail) includes all those ten-footed crustaceans which have the tail or post-abdomen at least as long as the body, and exposed and bent downwards towards the posterior extremity, and always composed of seven segments; and they have at the end of the tail, on each side, appendages ordinarily forming an instrument for swimming. The Macrura may be considered as forming a single genus, *Astacus*. The species are commonly known by the names of Lobsters, Cray-fish, Prawns, and Shrimps.

The family of Hermit Crabs (*Anomoura*) has the abdomen prolonged, but destitute of a shell, so that the tail is soft. They are remarkable for their habit of living in the deserted shells of mollusca, exchanging a less for a larger as they increase in size, and fixing themselves to their strange habitation by peculiar processes which seem developed for the purpose. 'The manœuvres of some of our native species, when they have outgrown their habitation, are quite ludicrous. Crawling slowly along the line of empty shells left by the last wave, and unwilling to part with their now incommodious domicile until another is obtained, they carefully examine one by one the shells which lie in their way, slipping their tails out of the old house into the new one, and again betaking themselves to the old one, if this should not suit. In this manner, they proceed till they have found a habitation to their liking.' They feed upon dead fish, and all kinds of garbage, thrown upon the shore; and when alarmed, they draw themselves closely into the shell, and close the aperture by placing their claws over the entrance.

Order Stomapoda (στόμα, a mouth, and πούς, a foot), commonly called *Sea Mantes*, comprehends crustaceans possessing maxillary feet formed like the first of the thoracic feet. Their gills are naked, and adhere to the five pair of appendages attached beneath the abdomen or tail. These appendages are used in swimming—in other words, they are fin feet. The *Cancer Mantis* is the type of the order; it is about seven inches in length. Its great claws have at the base three movable spines, and the terminal joint has six long and very sharp spines, of which the terminal is the strongest. This species is common in the Mediterranean.

Order Amphipoda (ἀμφίς, on both sides, and πούς, a foot—feet diversely conformed) are small animals, mostly marine, which sometimes are found in brooks and fountains. The majority swim and leap with agility, and always on their sides. The species best known in Britain is the Sandhopper, which burrows in the sand, and seldom enters the water. It feeds on mollusks and fish.

Order Læmodipoda (λαιμός, the throat, and πούς, a foot). These crustaceans have the head confluent with the first segment of the thorax, and supporting the four anterior feet. The posterior extremity of their body exhibits no distinct branchiæ. The Læmodipods are *of small size, all marine animals*, and parasitical; many of them live upon cetacea. The fishermen call them *whale-lice*. Sometimes these creatures are so abundant on the whales, that the individuals they infest may be easily recognised at a considerable distance by the white colour these parasites impart to them. When they have been removed, the surface of the body of the whale is found to be deprived of its outer skin.

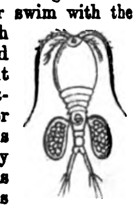


Cyamus Balænarum.

Order Isopoda (ἴσος, equal, and πούς, a foot) comprehends such crustaceans as have the legs all alike, and adapted only for locomotion and grasping. Their bodies are broad and depressed, and they do not leap. The greatest number of the species are aquatic.

The *Entomostraca* are divided into two Orders. The crustaceans of this section are in general so small, that the details of their structure can only be examined by the microscope. The legs, except in a few, are only fitted for swimming, and are variable in their number; some species have only six, others from twenty to forty-two, or even more than a hundred. They mostly inhabit fresh water. The Entomostracans are divided into two Orders—*Branchiopoda* and *Pœcilopoda*.

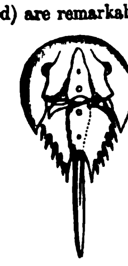
Order Branchiopoda are so named because the locomotive extremities fulfil the functions of gills. The majority of the animals of this order swim with the back downwards, darting about with great agility, and moving backwards and forwards with equal ease. Many exhibit only one eye, as in the family *Monoculidæ* (μόνος, one, and *oculus*, an eye), or Cyclopes. The type of this family is the *Cyclops Quadricornis*. It is very common in the ponds and ditches of this country. One species of this family is found in such inconceivable profusion beyond 42° of south latitude in the Pacific and Atlantic Oceans, that it gives the surface of the sea a red tint, and serves as food for whales.



Cyclops Vulgaris, magnified.

Order Pœcilopoda (ποικίλος, various, and πούς, a foot) includes such Entomostracous Crustaceans as have feet of different forms and uses; the anterior, of indeterminate number, serving either for walking or seizing, and the posterior feet branchial, and fitted for swimming. They live chiefly as parasites upon aquatic animals, and mostly on fishes. This order may be divided into two families—*Hyphosura* and *Siphonostoma*.

The family of *Hyphosura* (web-tailed) are remarkable for having the shield terminated by a very powerful horny, movable spike, like a sword. They are of a large size, sometimes measuring two feet in length. They compose the genus *Limulus* (*limus*, mud), commonly known by the name of King Crabs, or Crabs of the Moluccas, in the neighbourhood of which they are very abundant. They chiefly inhabit tropical seas, and are found near the shore. In China, their eggs are eaten, but their flesh is given to pigs. Savages make use of the horny style at the extremity of the body for arrow-points and spear-heads.



Limulus Polyphemus.

The family *Siphonostoma* are so named from their siphon-shaped mouth, which is fitted for suction. Their shell is very slender, and of a single piece. They are all

parasites, and are known by the name of *fish-lice*. They are found upon perch, pike, and carp. They also occur occasionally upon the cod; but they are never seen within the gill covers.

The **Cirrhopoda** (*cirrus*, a tendril, and πούς, a foot) are a family of Crustacea, of such peculiar and dubious form that till lately they were classed as mollusks. By some naturalists, however, they are considered as a distinct class. They are best known by the appellation of Barnacles. Entirely marine, they, in their mature state, attach themselves to rocks, pieces of floating timber, or the bottoms of ships, and even to the backs of other animals, where they find a diminutive prey. The remarkable feature of their external appearance, which has created such doubts respecting their proper place in the Animal Kingdom, is a many-valved shell, two of the pieces of which greatly resemble those of the common muscle.

This class is divided into two Orders—Barnacles (*Lepadites*) and Acorn-shells (*Balanites*).

The **Lepadites** comprise the Cirrhopods which are elevated upon a fleshy flexible contractile stem, attached by its base to some solid body, and supporting at its extremity the principal parts of the animal, enclosed by a multi-valve shell or leather-like case. The species most widely spread in our seas is *Lepas anatifera*—literally, the goose-producing; a name which records one of the most remarkable delusions of the early observers of animated nature. It was fully believed in the sixteenth and seventeenth centuries, and set forth on many trustworthy testimonies, that a particular species of goose originated in these shell-fish, and this bird was on that account called the *Barnacle Goose*. The authors of this fable must have been misled by some slight and accidental resemblances.

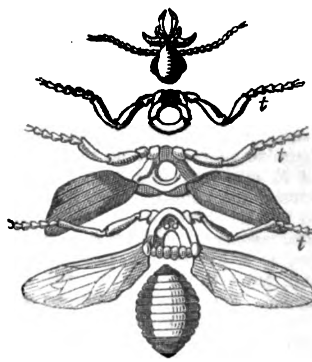
Order Balanites, or *Acorn-shells*.—In these the *shell* is attached to some solid body. In other respects, they differ little from the former order. The rocks, shells, and piers of all our coasts are in a manner covered with a species of the *Lepas balanus*. Others plant themselves on the skin of whales, and penetrate into their lard.

CLASS INSECTA.

The **Insecta**, or Insects, are a class of such endless variety of forms, that zoology would be a great branch of human knowledge if it comprehended them alone. The insect may be described as an articulate animal, with a body of three parts—head, thorax, and abdomen—and three pair of legs; having a peculiar breathing-apparatus of tubes distributed through the body; and generally, but not in all instances, furnished with one or two pair of wings, by which it is enabled to spend a portion of its time in the air. It is also distinguished by undergoing metamorphoses, or changes of form, between its leaving the egg and attaining its adult condition; that is to say, it emerges from the egg into the *larva*, or caterpillar, with all the appearance of a simple grub, in which condition it feeds voraciously and grows rapidly. It then passes into the *pupa* or *chrysalis* state, being cased up in a coriaceous or leather-like covering, like a mummy, and seems all but devoid of life. Finally, it emerges from this condition as the *imago* or perfect insect. There are, however, varieties in these conditions. The larvæ of some insects, for example, reside in tubes which they construct for themselves (the *caddis-worm*); some spin a thread from their bodies, and winding this into a kind of case or cocoon, spend their time therein till ready to come out as perfect insects (the *silk-worm*).

From the great variety of species in the Insecta, and the great fecundity which belongs to most of them, they form a prominent and most important part of creation. 'To leap, to run, to walk, to bore into the ground or drive galleries through timber, to fly through the air, to gambol in the water, to dive and swim, are amongst the endowments of insects. Some build structures more wonderful than the Pyramids, while others construct habitations with mathematical accuracy, and have streets and palaces bearing no slight analogy to those of human communities. Some gleam with phosphorescent radiance, or flutter about painted in all the glories of the rainbow. They furnish us with silk, wax, honey, lac, cochineal, and gall-nuts. Some hold a most important place in the pharmacopœia, and most of them furnish food to the beasts of the earth and birds of the air, to the fish and reptile tribes, and to some of the more powerful of their own class.'

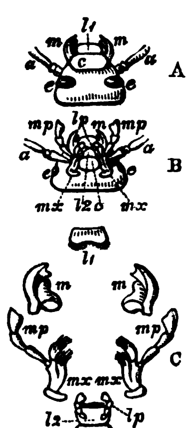
The larva always consists of twelve ring-like sections, exclusive of a head. These twelve sections are still to be traced in the perfect insect, three of them being comprised in the thorax, and the remainder in the abdomen. From each of the three sections of the thorax proceeds a pair of legs, and the second and third usually give origin to a pair of wings each. In the accompanying sketch of the parts of the perfect insect, the three sections of the thorax (*t t t*) are represented apart, with the legs and wings attached to them.



Segments of an Insect.

Insects in their perfect state are distinguished beyond all other animals by their powers of locomotion, and the perfection of their instinctive actions. Their senses appear to be acute. They have generally large eyes, formed by the union of a great number of small ones, presented in different directions, so as to secure a great range of vision. Organs of hearing and smell are believed to exist, though they have not been satisfactorily detected. That there is a delicate sense of touch, is not to be doubted; and from observations made on bees and ants, there is reason to believe that they communicate with each other by this sense. A prominent feature of the head of many insects is a pair of *antennæ*—jointed instruments of various forms—which are evidently used as exploratory organs; of a similar character and similar use are two pair of *palpi*, or feelers, attached to certain parts of the mouth.

In four orders of insects, the mouth is furnished with an apparatus fitted for chewing and bruising the substances on which the animals are intended to feed. In five other orders, there is a proboscis or *haustellium*, for sucking up juices. The first kind of apparatus consists of six principal pieces, the chief being a pair of *mandibles* or cutting instruments, which work against each other, much like a pair of scissors, and sometimes end in hooks, more formidable, for the size of the animal, than the teeth of the tiger. Where, from the presence of a sucking-instrument, the mandibles are not required for eating, they are used variously as trowels, spades, pickaxes, saws, or knives, in the construction of habitations. In the annexed illustration will be found the various parts of the mouth of one of the mandibellate orders—a beetle.*



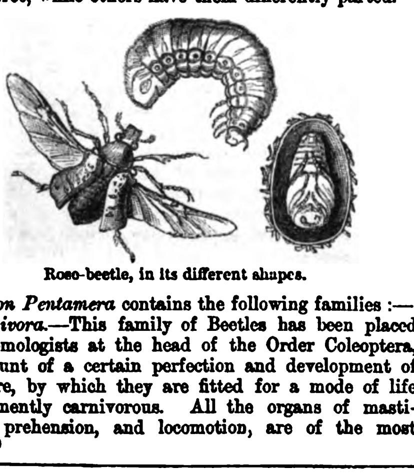
* A, upper side; B, under side; C, parts separated: *aa*, antennæ; *ee*, eyes; *l1*, upper lip; *mm*, mandibles; *mx*, maxillæ; *mp*, maxillary palpi; *l2*, labium; *lp*, labial palpi; *c*, *c*, *c*, chin or mentum.

ORDER COLEOPTERA (κολεός, a sheath, and πτερόν, a wing) comprehends those insects in which the first pair of wings are crustaceous, and serve as defensive coverings to the true wings while at rest, but allow them their proper play when flying. In many instances, however, this is not a correct definition of the order, as some are without wings and sheath; and in many others the latter only is present. The body is also covered with an integument of a similar nature. By means of this crustaceous covering to their wings, beetles are enabled to burrow in the soil, or bore the trunks of trees, without injuring their delicate organs of flight. A beetle, Swainson says, is an insect cased in armour of proof. Let us take a chafer, for instance, or one of those dors whose 'drowsy hum' breaks the stillness of a summer's eve, and examine it closely. With what admirable precision do all the parts of its armour join and fit into each other! It will be almost impossible to insert the point of a pin between any of the joints, and yet the insect moves about without the slightest embarrassment. Not only is every joint, the most minute, either of the antennæ or palpi, completely cased, but even the eyes are often defended in the same manner. They have the hardest covering of all insects—just as the armadillos among quadrupeds, or tortoises among reptiles.

The Coleopterans are, of all the orders of insects, the most numerous and the best known. In Britain, they compose nearly a third part of our entire insect population; and the singular forms and brilliant colours which many of them possess, arrest the attention even of persons comparatively indifferent to the wonders and beauties of nature. With respect to their colouring, an eloquent author says: 'Sometimes they resemble the clouds of heaven; at others, the meandering course of the rivers of the earth, or the undulations of their waters; many are veined like beautiful marbles; others have the semblance of a robe of the finest net-work thrown over them: some she blazons with heraldic insignia, giving them to bear in fields sable, azure, vert, gules, argent or or, fesses, bars, bends, crosses, crescents, stars, and even animals.'

Beetles undergo a complete metamorphosis. The larva envelops itself in silk, makes a covering of leaves; or burrows in the earth, where it undergoes its change into an inactive pupa, and in due course it assumes its last and perfect form. This Linnæus termed *imago*, because, having laid aside its mask, and cast off its swaddling-bands, no longer disguised or confined, or in any respect imperfect, it is now a true representation or image of its species.

The primary division of beetles is founded upon the number of joints in the divisions of their feet, or *tarsi*, as they are called; some having five, some four, and some three, while others have them differently parted.



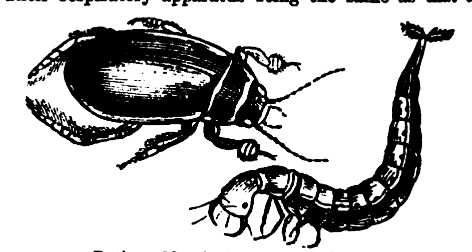
Rose-beetle, in its different shapes.

Section Pentamera contains the following families:—

Carnivora.—This family of Beetles has been placed by entomologists at the head of the Order Coleoptera, on account of a certain perfection and development of structure, by which they are fitted for a mode of life pre-eminently carnivorous. All the organs of mastication, prehension, and locomotion, are of the most efficient kind. Of these the most conspicuous are the mandibles which project from the head, and are armed with strong and powerful teeth. Like the carnivora of the mammals, these insects are remarkable for the beauty of their colours, from which they have derived the name of *Tiger-beetles*. They prey indiscriminately on other insects, and there are few that can resist their attack. Even their larvæ are predatory. In this stage, they dig cylindrical holes for themselves in the earth, nearly vertical. This they accomplish with their feet and jaws; at intervals carrying up the earth they detach on the concave part of their head, and throwing it off by a jerk. In these holes they lie in ambush, ready to seize such unwary insects as come within their reach. 'As the excavation is nearly perpendicular at its mouth, they would have difficulty in retaining their position were it not for their dorsal spines, by which they suspend themselves to the side of their dwelling.' The flat plate of their head exactly stops the mouth of the hole, and forms an even surface with the surrounding soil. When they are about to undergo the change to the pupa state, they seal up the entrance of their dwelling, and retire to its innermost recess.

The Common Beetle (*Cicindela campestris*) is half an inch in length, of an obscure green above, and each elytron, or wing-covering, has five small white dots. These beetles are usually found in sandy fields, or in heaths exposed to the sun. Another beetle of this family is the *Carabus clathratus*, remarkable for its brilliant colours.

Family *Dytiscidæ* (Δύτης, a diver).—The beetles of this family are aquatic in their habits. They have the feet fringed with long stiff hairs, which present a broad surface to the water, otherwise there is little difference in their structure from the former family. Their respiratory apparatus being the same as that of



Dytiscus Marginalis—Larva and Imago.

other insects, they are obliged to repair from time to time to the surface of the water in order to breathe. The larvæ suspend themselves at the top of the pool by means of two appendages at the sides of the tail; but when the period of their transformation arrives, they betake themselves to the land, and burrow in damp situations in the adjacent banks.

Brachelytra are so called from having short crustaceous wing-coverings. Their body is narrow and elongated, and bears some resemblance to the earwig. This family consists of only one genus—*Staphylinus*. One of the largest species of this genus is frequently seen running about garden-walks.

Serricornes (*serra*, a saw, and *cornu*, a horn).—This family comprehends such as have serrated or saw-shaped antennæ, and the elytra completely covering the body. The wire-worm, so well known in this country, is the larva of the *Elator obscurus*. The damage it occasions by devouring the roots of corn is sometimes of vast extent, and attended by most disastrous consequences.

Another interesting genus is the *Lampyris*, or Glow-worm, so remarkable for the brilliant light which it emits at night. The body of this beetle is soft, and the light resides in the two or three last sections of the abdomen. The female especially possesses the luminous property. They are often employed by the inhabitants of those countries where they prevail, as a

substitute for artificial lights. Southey refers to them in his *Madoc*, as furnishing the lamp by which Coatel rescued the British hero from the hands of the Mexican priests:

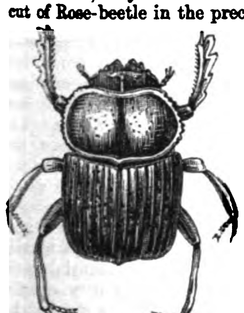
'She beckoned, and descended, and drew out
From underneath her vest a cage, or net
It rather might be called, so fine the twigs
Which knit it, where, confined, two fireflies gave
Their lustre. By that light did Madoc first
Behold the features of his lovely guide.'

The Death-watch (*Annobium pertinax*) derives its specific name from the pertinacity with which it feigns death, 'preferring to be roasted by a slow fire rather than shew the least sign of life.' In the larva state, it employs itself in perforating furniture and books, which, when they have suffered much in this way, are said to be *worm-eaten*. The noise which the little animal makes with its jaws in this work, resembles the ticking of a watch, and is heard whenever an unusual silence prevails. As this is usually the case in a sick-chamber, the noise is apt to be heard before any one dies, and, by a natural process of the ignorant mind, is held to be a warning of death. Hence the name of *death-watch*.

The family *Claricornes* are characterised by having the extremities of the antennæ thick, and often terminated by a perfoliated or solid mass. They are partly terrestrial and partly aquatic. The most remarkable genus of this family are the Burying-beetles (*Necrophorus*), so called from their habit of burying small quadrupeds, such as mice and moles. When they find a carcass, they creep beneath it, and dig away the earth till the hole is sufficiently deep to receive it. After it is intombed, they deposit their eggs in the carcass, upon which the young feed during their larva state.

The family of *Palpicornes* possess, like the last family, long antennæ, terminated in a club, which is commonly leaf-like. The body is generally ovoid. Their feet are suited for swimming. The genus *Hydrophilus* comprises the largest species in the tribe. *H. Piceus* is an inch and a half long, oval, of a black-brown colour. It is common in Britain, frequenting ponds and ditches. It swims and flies well, but walks badly. The females construct cocoons of silk; the outer surface is coated with a gummy matter, which renders it impervious to the water on which they float.

The family of *Lamellicornes* are so called from the antennæ terminating in a club or large knob, composed of laminæ or thin plates, arranged like the leaves of a book, which they can open or shut at pleasure. They feed entirely upon vegetable matter, either in a green or decomposed state. Among them we find great diversity of form, size, and colour. The *Cetonia aurata*, or Common Rose-beetle, may be taken as the type of the whole. See cut of Rose-beetle in the preceding page.

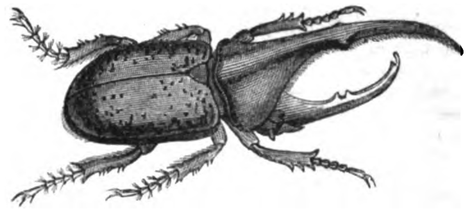


Ateuchus Sacer.

The sacred Egyptian Beetle (*Ateuchus sacer*) was one of the creeping things to which that remarkable people paid divine honours. It was consecrated to the sun, and was therefore regarded as the emblem of fertility.

Some of the best known of our native Coleoptera belong to this family—as the Stag-beetle and Cockchafer. The Stag-beetle (*Lucanus cervus*) is a very large insect, the male measuring two inches in length. It is found in the southern counties of England. It pierces the bark of trees, and lives on the sap. The Cockchafer (*Melolantha vulgaris*) abounds in England, but is rare in Scotland. In its larva state it consumes the roots of grass and other herbaceous plants. The perfect insect is equally destructive to the leaves of our forests and woods.

A most remarkably formed species is the *Dynastes Hercules*, a native of Brazil, which attains the length of five inches, and of which the male possesses an enormous horn projecting from the head, which is opposed by a corresponding protuberance from the thorax.



Dynastes Hercules.

Having described the habits of a few of the beetles, we shall give little more than the classification of the remainder.

Section Heteromera.—The name signifies that the legs have a different structure from one another: while there are five articulations in the first four tarsi, there are only four in the hindmost pair. They are terrestrial in their habits, and chiefly dwell in dark places, such as cellars, stables, and the like. Their food consists of vegetable substances. This section comprises four groups.

Melasoma, as their name implies, are for the most part black, or of an ashy colour, and unvaried. They are distinguished also by hard wing-coverings, wings generally wanting, claws simple, and maxillæ with a hook. They live for the most part in the ground beneath stones, or in the sand, and in low and dark parts of buildings, and are very tenacious of life. The *Blaps mortisaga* is a well-known example, being often found in dark and dirty places about houses.

Another, *Tenebrio molitor*, is very common in England, being found, especially in the evening, in bakehouses and corn-mills. Its larva, called the meal-worm, is long, scaly, and smooth.

Taxicornes (*taxus*, a yew-tree, and *cornu*, a horn) includes those coleopterous insects in which the antennæ gradually augment in size as they extend from the head, or terminate in an enlargement. Their claws are simple, and maxillæ without a hook. They are generally found in the fungi which grow on trees, or beneath the bark. Examples—*Diaperidæ* and *Copyphidæ*.

Stenelytra (στινὸς, narrow, and ἔλυτρον, a sheath) are so called from the wing-coverings being narrow at the posterior part of the body. Examples—*Helopidæ* and *Cistelidæ*.

Trachelides (τράχηλος, a neck).—The insects of this section have the head supported on a kind of pedicle or neck. Examples—*Meloë*, *Mordellattoria*, and *Lagria*. The Blister-beetles (*Meloë vesicatorius*) are more plentiful in Spain than in any other country of Europe, and are well known by the name of Spanish Flies. They are collected for commercial purposes, chiefly in the month of June. They are shaken from the branches of trees and shrubs which they frequent, such as the ash and lilac, and received in sheets spread upon the ground. They are then killed by being held in hair-sieves over the fumes of vinegar, and afterwards dried either by exposure to the sun, or by being placed on hurdles covered with cloth or paper in a well-ventilated apartment.

Section Tetramera contains such beetles as have four joints in each foot. They all feed upon vegetable substances. The perfect insect is found upon the flowers or leaves of plants, while many of the larvæ occupy the interior of fruits or seeds, where they have been deposited by the mother, and furnished with a house of defence and food for their support. This section is divided into seven families, the chief of which is that of the *Curculionidæ*, or Weevils. These are easily

distinguished from other beetles, by the prolongation of the anterior part of the head into a kind of muzzle. They include some of the most dangerous enemies to our vegetable stores. Another family, *Xylophagi*, have their name from the habits of their larvæ as destroyers of wood. A third, the *Longicornes*, are remarkable in the same way; of this family an English species, *Callichroma moschata*, is beautifully coloured, and exhales an agreeable musky odour.

Section Trimera, or the Beetles which have only three joints.—This division is of comparatively limited extent. To it belong *Fungicolæ* (*fungus*, a mushroom, and *colo*, I inhabit); found on mushrooms. A pretty little species of this family found in England is the *Coccinella vigintiduopunctata*, so called from its having eleven white spots on each wing covering. The *Aphidiphagi* prey upon aphides, or plant-lice.

ORDER ORTHOPTERA have the wings, when at rest, disposed in straight longitudinal folds: hence the name. The wing-coverings are called tegmina. These consist of a stiff substance resembling parchment, and serve the purpose not only of protecting the inferior wings, but also of assisting in flight. The Orthopterous insects are terrestrial in all the stages of their existence. Some are carnivorous, or omnivorous; but the greater number feed on living plants. Their mandibles are large, powerful, and efficient.

This order consists of two sections. The first of these, *Cursoria*, have the hind-legs entirely fitted for running, and are divided into four families.

Family *Forficulidæ* (Earwigs) 'are furnished with ample and curious wings, the principal nervures of which are so many radii diverging from a common point near the anterior margin. Between these are others, which, proceeding from the opposite margin, terminate in the middle of the wings. These organs, when at rest, are more than once folded, both transversely and longitudinally.'

Family *Blattidæ* (Cockroaches) are nocturnal insects, certain species of which infest kitchens, bakehouses, and corn-mills, while others are found in the fields. Most of them are of a uniform brown colour; their wing-covers are generally as long as the abdomen, and their wings are folded only longitudinally.

Family *Mantidæ* are characterised by a narrow body, and their legs are unequal; the anterior pair, which are serrated, being longer than the others. They are all carnivorous in their habits, as might be inferred from their large mandibles; and are so pugnacious, that in China the children keep them in small cages, and amuse themselves by putting two together, when they immediately fight like game-cocks. Roësel, who kept some of these insects, observes, that in their mutual

Mantis Religiosa.

conflicts, their manœuvres very much resemble those of hussars fighting with sabres. Sometimes one cleaves the other through at a single stroke of its leg, or severs the head from the body. One species, the *Mantis religiosa*, is regarded by the inhabitants of the countries it inhabits with superstitious reverence, on account of its attitude, recalling the appearance of a man engaged in prayer. This is, however, the position in which the creature lies in wait for its prey. They are chiefly confined to the tropical and warm regions of the globe.

Family *Phasmidæ* (or Spectre Tribe).—This family is distinguished from the Mantidæ by having all the legs of equal dimensions, or nearly so. Their mandibles are, however, adapted for gnawing. They live exclusively on vegetables. This family is rarely found beyond the tropics. Some of the species surpass all other insects in length. *P. Gigas* is said to measure nine inches from one extremity to the other. Another species is remarkable for the similarity its wing-coverings bear to a laurel-leaf.

Section Saltatoria consists of three families.

Family *Achetidæ* (the Cricket Family) are a very noisy race. The chirping of the House-cricket, *Gryllus domesticus*, is heard, under favourable circumstances, at a distance of more than a hundred yards. The noise is produced by the friction of the elytra cases against each other; and though harsh, gives life to solitude, and conveys to the mind the idea of a perfectly happy being; hence the expression, 'as merry as a cricket.' It is found chiefly in bakehouses, and feeds on insects. The Field-cricket and Mole-cricket also belong to this family.

Family of *Gryllidæ* (Grasshoppers) are distinguished by very long antennæ, always as long as their body, and frequently even of greater length. The head is perpendicular, or slightly incurved. They are all herbivorous. Few of them inhabit this country; and such as we possess are of small size, compared with those of foreign lands. These are the little chirpers which we hear in heaths and sunny banks. They begin their song long before sunrise: in the heat of the day it is intermitted, and resumed in the evening.

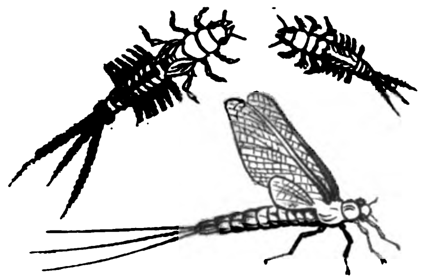
Family of *Locustidæ* (Locusts).—Their antennæ seldom exceed half the length of the body. They have coloured elytra, and large wings, disposed when at rest in straight fan-like folds. They fly by starts, but frequently rise to a great height. 'Certain species unite in vast numbers, and emigrate, resembling a dense cloud in their passage through the air. Wherever they alight, all signs of vegetation disappear, and cultivated grounds are left a desert.'

ORDER NEUROPTERA (Nerve-winged Insects) are characterised by four naked membranous wings, reticulated or interlaced with a delicate net-work, and fully fitted for flight. In general the wings are of an equal length, though in some families the posterior pair are smaller than the others, and in a few cases they are entirely wanting. Some of the Nerve-winged Insects pass through a semi-metamorphosis merely; the rest undergo a complete transformation. The majority of them are carnivorous in the larva state, as well as when they are perfect insects.

The family of *Libellulidæ* (Dragon-flies) are distinguished by the slender form of their body, and beautiful and varied colouring. Their wings are large, and generally extended horizontally, and at right angles to their body during repose. In velocity and protracted duration of flight they excel all other insects, and they can dart backwards or sidewise with equal ease. In the first two stages of their existence, Dragon-flies live entirely in the water; and when they become winged insects, they haunt the precincts of that element on all occasions. At the time of oviposition, the female places herself upon a plant close to the edge of the water, into which she thrusts the extremity of her body and deposits her eggs.

Family *Ephemeridæ* (ἐφ'=ἐπί, upon, and ἡμέρα, a day), Day-flies, are so called from the short duration of their life in the perfect state, which is frequently

limited to twenty-four hours; though as larvæ their existence extends throughout two or three years. They



Ephemera Vulgata—Larva, Pupa, and Imago.

carry their wings always elevated perpendicularly. They are seen in summer and autumn sporting in every variety of evolution over ponds and brooks. The May-flies (*Ephemeres albipennes*) are the largest of the British species, both in the larva state and as perfect insects. They are a favourite food of the fresh-water fishes, and on this account form excellent bait for anglers.

Family *Termitidæ*, White Ants (*termes*, the branch of a tree), are so called because some of them affix their nests to branches. They are terrestrial, and carnivorous or omnivorous in all their stages; and perform a considerable share in the labour of completing the comminution and destruction of dead and decomposing organised matter. They are the only insects of the order that exhibit social habits.

When arrived at their perfect state, the Termites quit their habitation, and fly abroad during the evening and night, but lose their wings before morning, and falling to the ground, numbers of them become the prey of birds and lizards. The workers collect as many of the females as possible, and enclose them in large cells, in order to the establishment of fresh colonies. Although probably all are of tropical origin, a few species have located themselves in the south of Europe.

Family *Myrmelionidæ* (Ant-lions).—The destruction which their larvæ make amongst ants has gained for them their family name. The economy of these insects in their larva state is very interesting. They inhabit dry sandy situations, where they form a funnel-shaped hollow, the top of which is sometimes a foot in diameter, the sides being formed of such loose sand, that any

Ant-lion.

insect approaching the edge inevitably slides down. The ant-lion, having stationed itself at the bottom of the hole with the jaws only exposed, is ready to seize its prey, which, when obtained, it sucks completely dry. Having thus exhausted its juices, the husk is placed upon its head and legs, and a sudden jerk casts it beyond the outer circle of the pitfall. When the ant-lion attains its perfect state, it loses its carnivorous propensities, and revels upon the nectar of flowers. It rarely flies during the day, but chiefly towards the evening. The common European species, in its perfect state, is about an inch in length. Its wings are transparent, black, and dotted with white.

ORDER HYMENOPTERA, or Membrane-winged Insects, resemble the Neuroptera, but cannot well be mistaken for them. The anterior and hinder wings, the former of which exceeds the others in size, are in flight hooked together, so as to produce one continuous margin. These organs exhibit fewer nerves than in the former order. Though considered as mandibulate insects, the Hymenoptera have the maxillæ modified in such a way as to enable them to live in a great degree by suction. A more distinguishing characteristic is perhaps the appendage at the tail, either in the form of a sting or ovipositor. They are distributed over the whole world; and some of them, by their production of wax and honey, are exceedingly serviceable to man. When we add that the order comprises Bees, Ants, Gall-flies, Wasps, and Ichneumons, it will be apparent that the Hymenoptera possess instinct in a higher degree than any other kind of insect.

This order has been divided into the following families:

Family *Tenthredinidæ* (Saw-flies).—The female insects of this family are furnished with an ovipositor—an instrument placed at the extremity of the abdomen, combining the properties of a saw and a file. By its means, the insect makes a succession of small holes in the branches or other parts of trees, in each of which an egg is deposited, accompanied with a drop of frothy liquid, which closes up the hole. Sometimes, however, the ova are attached to leaves. An instance of the former mode of oviposition is observed in the Rose Saw-fly; while a familiar example of the latter is found in the species which infest gooseberry and currant bushes. The larvæ of this family bear a strong resemblance to the caterpillars of butterflies and moths, but are easily distinguished by the number of their feet, being from ten to sixteen.

Family *Ichneumonidæ* (Ichneumons) have obtained their name from the Ichneumon quadruped which destroys the eggs of the crocodile while they are hatching in the sand, and thus limits the increase of that formidable reptile. In a similar manner, the Ichneumonidæ are useful in diminishing the numbers of destructive insects. This family is so numerous, that scarcely an insect exists which in its larva state is not exposed to the attacks of one or other of the species. Inserting their stings into the larvæ of other insects, they there deposit their eggs, where the young, when hatched, find a sufficiency of food. The grub ultimately falls a victim to its ravages; but this event seldom takes place till the young Ichneumons have attained their full growth; and, what is very remarkable, they carefully avoid injuring the vital parts of the larva on which they prey.

Family *Cynipsidæ* (Gall-flies).—These insects deposit their ova in living trees, and the irritation excited by their presence gives rise to the formation of excrescences, called *galls*, such as those so frequently observed on the leaves of the oak-tree. While some of these tumours resemble seed-vessels, others are of a globular form, a bright red colour, and smooth, fleshy consistence, resembling beautiful fruit. Their situation on the plant is also diversified —some being found on the leaf itself, others on the footstalks only; some on the roots, and others on the buds. 'Some of them cause the branches upon which they grow to shoot out in such singular forms, that the plants producing them were esteemed by the old botanists as distinct species.' The larvæ feed on the interior of their habitations, where they generally remain five or six months. Some undergo their metamorphoses within the galls, while others depart, in order to descend into the earth. The small round holes observed in the sides of these excrescences, shew that the insects have made their escape. Galls form an article of commerce; they are imported from the Levant, and used in the manufacture of writing-ink and black dyes.

Family *Formicidæ* (Ants), so celebrated for their industry, live in societies, often of great extent. In this and some other hymenopterous families, there is a curious and peculiar sexual arrangement—one large portion of each society being unfitted for reproduction

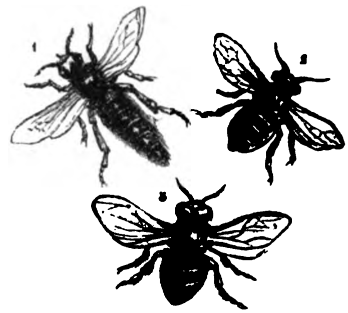
(neuters), and designed only to act as nurses of the young, the production of which is the duty of a limited number of true females. This duty of providing food for, or nursing the young, is what has given ants and bees their great reputation for industry. The males and females are found only temporarily in the ant's nest, from which they make their escape as soon as they have gained their wings. The males soon die. The females pull off their own wings with their feet, and become the founders of new and distinct colonies. The nature and form of the nest vary according to the instinct of the different species. They are most generally established in the ground, the nests being entirely hidden, or forming conical mounds; some inhabit the trunks of old trees, which they pierce in every direction.

The neuters feed the young grubs, and move them on fine days to the outer surface of the nest, in order to give them heat, removing them back at the approach of night or bad weather. They defend them from enemies, and take the greatest care of them and of the pupæ. The neuters pass the winter in their nests in slumber, with more or less pertinacity, according to the severity or mildness of the season.

The food of the ants consists chiefly of aphides or plant-lice. None of the European species hoard grain for the winter, but they display a sagacity no less wonderful in forming a provision for themselves. 'Many of them,' says Huber, 'collect the eggs of aphides, deposit them in their own nest, and guard them with the greatest care till hatched; and then, as we pasture milch kine, they continue to keep an eye over them, for the delicious nutriment they afford.' There is, however, a species in India which hoards up the seeds of grass, and to it the lesson of Solomon may have referred: 'Go to the ant, thou sluggard; consider her ways, and be wise: which having no guide, overseer, or ruler, provideth her meat in the summer, and gathereth her food in the harvest.'—*Prov.* vi. 6–8. Some ants are gifted with double means of annoyance, as they can sting as well as bite. Our indigenous species may be regarded as comparatively harmless.

The *Vespidæ* (Wasps) generally form large societies, composed of males, females, and neuters. A colony is commenced in the spring by a single female, which has lain dormant and survived the severity of winter. She lays eggs which soon produce neuters or labourers. Assisted by a numerous army of these coadjutors, she proceeds to enlarge the nest, by detaching particles of old wood or bark, and moistening and reducing them into pulp. This, when dried, forms a paper-like substance, suitable for the purpose of building. The neuters, under the guidance of the parent-wasp, tend subsequent broods till the beginning of autumn. The young males and females then appear abroad. The number of females in a wasp's nest generally amounts to several hundreds. Of these very few survive the winter; such as are so fortunate, remain torpid till the vernal sun recalls them to life and action.

Family *Apidæ* (or Bees) compose a large group, which are well known from the universal reputation of the typical genus *Apis*, of which the domestic bee is a species. Living in detached communities, under the apparent rule of an individual, the domestic bees furnish us with an emblem of monarchical government, whilst their steady industry in storing up provision for the contingencies of a barren period, has been the theme of sages and moralists, as an example for the indolent of their own species. The average number of each community has been computed at about 16,000. One only of each hive is a true female, distinguished by her size, and denominated the *queen*. About 600 are males, usually called *drones;* and the remainder, consisting of upwards of 15,000, are *neuters*, destined to labour. The queen, in the larva state, is furnished with a cell of royal dimensions, of a cylindrical form, and she is supplied by her nurses with food of the most nutritious and delicate kind, called by bee-farmers royal jelly, extracted from flowery juices. When arrived at full growth, she spins



1, Queen; 2, Drone; 3, Neuter Bee.

within her cell a silken shroud; therein she changes to a nymph or pupa, and in due time comes forth in all the dignity of majestic size and splendid colouring. The labouring-bees find themselves, when emerging from the egg, inhabitants of six-sided cells, so proportioned as to limit their growth, and prevent their full development; they are supported on the simple fare of bee-bread—a substance composed of pollen and honey. The males or drones exist only between April and August, when they are destroyed by the workers as useless.

The wax of which the bees construct the cells required for the storing of their honey and other purposes, is secreted by them in little scales, in which state it works out from between the segments of the abdomen. These are taken up and kneaded by the jaws, and applied in the proper place. The cells are built in a hexagonal, or six-sided form, being that which gives the nearest approach to the circular, with the least expenditure of material, and at the same time the greatest strength. The bottom of each cell on one side abuts against three on the other, and is supported by the divisions between them. It is formed of three plates meeting at an angle, and this angle has been ascertained, by a very intricate calculation, to be *precisely* that which enables the greatest strength to be obtained with the least material; the instinct of an insect thus coming to the very same result as the highest human intelligence. Some of the cells thus formed are employed as store-rooms for honey and pollen, and in others the eggs are laid. The eggs from which perfect females or queens are to be produced, are laid in cells much larger than the rest, and of different form; but if, from any cause, these should not afford a sufficient number, the bees have the power of rearing a female or queen from a neuter grub, by feeding it with an aliment more stimulating than the pollen. The drones are killed at the end of summer, but the queen and great part of the workers remain; and when, in the summer, they increase so much as to over-people the hive, colonies are sent forth with young queens in search of another habitation.

One of the most marked features of the wasps and bees, is the possession of a sting, situated where the ovipositor is placed in other hymenopterous insects.

The remaining orders of insects are *Haustellate*—that is, possessed of a mouth formed for suction.

ORDER HOMOPTERA have the fore-wings of the same consistence throughout, often somewhat parchmenty, and, when folded, they incline at an angle like the roof of a house. All the animals of this order feed on vegetable juices, for obtaining which their tongue is elongated and channeled like a gutter, and surrounded by delicate lance-like organs for piercing the tissue of plants. The females of some species are furnished with an ovipositor, provided with several toothed saws, by means of which they make punctures in the leaves and stems of plants, and thus introduce their eggs into a place suitable for bringing out the larvæ.

Family *Cicadidæ* have their type in the well-known *Cicada*, so much celebrated by the poets for its fine song. Most of the species are confined to warm climates, and only a small one exists in England. The shrill chirp of the cicada is alluded to by many poets. One bard entreats the shepherds, 'To spare that nightingale of the nymphs.' Anacreon calls it 'Sweet prophet of the summer;' and Virgil alludes to it when he says: 'Et cantu querulæ rumpent arbusta cicadæ.' Byron describes them as 'The shrill cicadæ, people of the pine.' No author has given a better idea of the singing of a cicada than old Marcgrave, who says its tune begins with *gir*, *gvir*, and continues with *cis*, *cis*, *cis*. The animal produces its sound by a peculiar apparatus situated beneath the abdomen. Among the Cicadidæ are found the largest of the homopterous insects, some species measuring seven inches across the wings.

Family *Aphides* (Plant-lice) inhabit trees or plants, to which, notwithstanding their generally small size, they prove highly destructive. They are frequently seen on rose-buds, and on the honeysuckle, presenting a green mass of moving life; and the sweet honey-dew which is found on the leaves of these plants, and various other trees, is a substance extracted by these little insects from the sap, and afterwards ejected in a state of the greatest purity.

Family *Coccidæ* (Blight Insects).—The males have only two wings, which lie horizontally on the body, one over the other. The females are without wings. The cochineal insect (*Coccus cacti*), a species of this family, is esteemed for the splendid colour it furnishes. It was first imported into this country from Mexico about the middle of the sixteenth century. The animals are scraped from the cactus plants, which they inhabit, into bags, killed by boiling-water, and dried in the sun. Though the Spaniards, on their arrival in Mexico in 1518, found cochineal dye employed by the natives, yet its true nature was not ascertained for nearly two centuries afterwards. Acosta, indeed, as early as 1530, stated it to be an insect; but Europeans generally, misled by its external appearance—resembling that of a reddish shrivelled grain—believed it to be the seed of a plant. The quantity annually exported from Mexico has been said by Humboldt to realise half a million sterling. It takes 70,000 insects to make a pound of cochineal. Another species, which belongs to the East Indies, produces gumlac, a substance made use of in the manufacture of beads, rings, and other ornaments; mixed with sand, it forms grindstones. In this country it is chiefly employed in the composition of varnishes, sealing-wax, and japanned or lacquered ware. A species in China is used for the manufacture of wax-tapers.

Family *Fulgoridæ* are distinguished by a curious prolongation of the forehead, which sometimes equals the rest of the body in size. In it is said to reside the luminosity which has given rise to the family name—a property, however, which has been doubted by many

Fulgora Laternaria.

naturalists. The species are all vegetable feeders, and greatly destructive. Some species in China make a certain compensation for this by producing a secretion, from which a fine white wax is manufactured.

Family *Cercopidæ* are insects of small size, remarkable for the grotesqueness of the forms which many of them assume. Some species inhabit this country, the larva and pupa being remarkable for causing that exspumation on plants which children call cuckoo-spit or gowk-spittle.

Order Heteroptera are the co-relatives of the Homoptera, being distinguished from them by having the fore-wings of diverse consistence, coriaceous at the base, and membranous towards the point. They are chiefly supported by vegetable juices; but some are remarkable for preying on the juices of the larger animals. The majority are confined to tropical climates, and the species which inhabit these regions are mostly ornamented with a great variety of beautiful colours and markings. In some species the wings are undeveloped, or the upper pair is wanting.

Family *Cimicidæ* (Bugs) are unhappily familiar to us, by the intrusion of a well-known species into our bed-chambers. It is believed that this disgusting insect was brought first to Europe early in the sixteenth century, by the return of the first voyagers from America. It has derived its name—Celtic for a hobgoblin—from its nocturnal and stealthy habits. The bite is generally attended by a poisonous effect, and there is a particular species said to be able to communicate a slight electric shock.

The *Water-bugs*, or *Boat-flies*, haunt the surface of still waters, moving rapidly along on their backs by means of their oar-like hind-legs, and using the front pair, which resemble a pair of hooks, in seizing small aquatic insects. They are furnished with wings, which they use in transporting themselves to new fields of depredation.

The *Nepidæ* (Water-scorpions) are fierce insects which lurk in the mud or weeds of ponds and streamlets, living solely upon insects. They seize and hold their prey with their long lobster-like fore-arms, and pierce it with their beak; a pointed hollow weapon serves the further purpose of sucking the juices of the struggling victim. Their prevailing colour is a blackish brown, scarcely distinguishable from the mud in which they love to lurk. In the twilight they frequently leave the water, for the purpose of seeking elsewhere a similar abode.

Order Lepidoptera (*Moths* and *Butterflies*) derive their name from a conspicuous peculiarity of their wings, the ordinary membrane of these organs being covered with a multitude of minute scales (λεπίς, a scale), set or planted therein, like the tiles on the roof of a house. The colours, which render the wings of many of the order so beautiful, reside in these scales, of which as many as 400,000 are reckoned to exist in a single silk-fly. The Lepidoptera subsist exclusively upon fluid nutriment, for obtaining which the maxillæ are so fashioned that they lock together with teeth into a single tube. All of this order are either males or females; neuters, which are so prominent among the Hymenoptera, are not found in the Lepidoptera. They go through a perfect metamorphosis. From the eggs deposited on the leaves of plants, proceed in due time the larvæ, or caterpillars, each species being generally placed on the kind of plant which it is fitted or inclined to eat. When it has attained its full size, it spins around its body a cocoon or case of silk, in which to spend its life as a *pupa* or *chrysalis*. This is an important habit on the part of the insect, as from one species we derive the silk which we weave into one of the most elegant kinds of cloth. The threads are formed by a glutinous secretion from glands, which seem analogous to the salivary glands of other animals; forced out through a small opening at the end of the lip, it hardens as it dries in the air. Some Lepidoptera form no cocoon, but hang in the pupa state by a thread from some lofty place. At the proper time, the perfect insect bursts from its case, to spend a brief gay existence in the air, to lay its eggs, and then perish.

Family *Papilionidæ* (or Butterflies), otherwise called

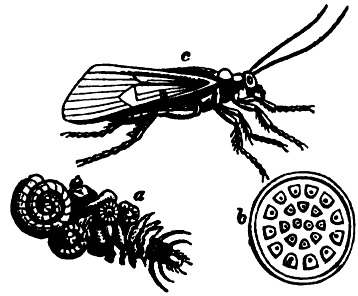
Diurna, are distinguished by the extraordinary beauty and variety of the colours which adorn their wings; and the number of species, each having some marked peculiarity, is enormously great. It is believed that not less than 2000 species exist in Britain alone. Beautiful as are many of these, there are still more splendid examples in other countries. Some of the foreign species exhibit an expanse of wing not less than nine inches; some display a metallic brilliancy of hue absolutely dazzling. The accompanying figure gives a good representation of the general aspect of the diurnal Lepidoptera.

Argynnis Paphia.

Family *Sphingidæ* (or Hawk Moths), otherwise called *Crepuscularia*, from their general habit of flying abroad in the twilight, live in much the same manner as butterflies. They are of a duller colour, and in flying make a loud humming noise. One species, noted for a skull-like patch of colouring on the back of the thorax, and thence called the Death's Head Moth, emits a squeaking kind of sound. In consequence of the peculiar aspect of its body, the sudden appearance of this insect has been popularly regarded as ominous of evil. It has a really formidable character towards bees, whose hives it enters boldly, scattering the inhabitants in alarm, and then preying upon the honey.

Family *Nocturna* (or Moths Proper) fly only by night, and are of a dull style of colouring. The most important tribe is that of the *Bombycidæ*, comprising the silk-worm and allied species. The silk-worm (*Bombyx mori*) is a native of China, where it has been domesticated for at least 3000 years. It was imported to Europe in the reign of the Emperor Justinian, 550 A.D. The caterpillar of the silk-worm, when it has attained its full growth—about three inches in length—proceeds to enclose itself in an oval-shaped ball or cocoon, preparatory to its assuming the state of the chrysalis or moth. The cocoon is formed by an exceedingly slender and long filament of fine yellow silk, emitted from the stomach of the insect. After emancipating itself from its silken prison, it seeks its mate. In two or three days afterwards, the female having deposited her eggs, from 300 to 400 in number, both insects terminate their existence.

The *Phryganea* is the type of a family, which some naturalists have placed as a distinct order, under the name of *Trichoptera;* while others assign it a place among the *Neuroptera*. The insects resemble the Lepidoptera in the distribution of the nerves of the wings, and the hairy covering with which both the wings and bodies are beset. The most remarkable peculiarity is seen in the larva state, when the creature —recognised as the Caddice-worm—resides in a cylindrical case, open at each end, to which they attach bits of stick, weeds, pebbles, or even small living shells, by the assistance of silken threads which they spin from their mouths. With the first three segments of the body protruded, they creep about with this case to feed, but withdrawing to the inside on the least alarm being given. When about to assume the pupa state, they fix their cases to some solid substance beneath the water,



Phryganea Grandis:
a, Larva in its case; *b*, Grating; *c*, Imago.

and close the two extremities with a kind of grating, so as to keep out everything but the water, which they require for respiration. Finally, in due time ascending to the air, they pass into the perfect state.

ORDER DIPTERA (or Two-winged Insects) are generally characterised by the peculiarity from which the name of the order is derived. The two wings correspond to the anterior pair in four-winged insects; besides which there are two short clubbed appendages, called balancers, which seem to be the rudiments of the posterior wings of other orders. Their mouth is formed for sucking, and their eyes are directed laterally.

Family *Culicidæ* (Gnats) are the most highly organised of all the Diptera; and the perfection of their suctorial apparatus, which is furnished with six lancets, many of us can attest from our individual experience of what is called the sting of a gnat. Their larvæ are aquatic, being those singular little red worms, thick at one extremity, which we frequently observe in stagnant waters. They move by a sort of jump, and are seen frequently resorting to the surface to imbibe a fresh supply of air. In their perfect state, they abound principally in the neighbourhood of water and marshy places. In Marshland, in Norfolk, the inhabitants are so annoyed by the gnats, that the higher classes, as in many hot climates, have recourse to a gauze-covering for their beds, to keep them off during the night.

Gnat.

The Mosquitoes are another species of the same family, which in many parts of the world interfere so much with our ease and comfort as to become one of the worst of pests, and a real misery of human life. They are very common in the woody and marshy parts of all hot countries; also abounding during their short summer throughout Norway, Lapland, and Finland. The Midge, so well known for its aërial dances, is the smallest species of the family.

Family *Tipulidæ* (or Water-spinners).—The most familiar species of the family is the *Harry Long-legs*. Many of the Tipulidæ in their larva state are very injurious to the roots of grass; others to the wheat-crops, by depositing their eggs in the centre of the corolla. They form a large tribe, subdivided by structure, but named from the places or substances they frequent: thus we have *Culiciform tipulæ*, *Terricole tipulæ*, *Gallicole tipulæ*, and *Floral tipulæ*.

Family *Tabanidæ* (or Gadflies) have highly organised mouths, the sucker being provided with six lancets. Many of them feed upon the blood of mammalia, and even of man himself. In the woods, in summer, they alight upon our face and hands, and put us to considerable pain. It is related that Messrs Kirby and Spence were frustrated in an entomological excursion by the prevalence of these insects, against the severe punctures of which they could find no protection. The Cleg (*T. pluvialis*) is the most common insect of the family.

Family *Œstridæ* (or Bot-flies) are all parasitic in some part of the body of mammalia. Most of them lay their eggs in the skins of animals, which they pierce for that purpose. This of course causes considerable pain, and the animals resort to many manœuvres to evade their tormentors. There are others, however, which deposit their eggs among the hair in situations where they can be licked off. These are swallowed, and hatched in the stomach, to the inner membrane of which the larvæ attach themselves, producing the disease termed the *bots* in horses.

Family *Muscidæ*, or Flies (*Musca*, a fly).—The most familiar species are the House-fly (*M. domestica*), and the Meat-fly (*M. vomitoria*). The first of these are great torments—not that they bite, sting, or hurt, but that they buzz, tease, and swarm on everything eatable. The larvæ are bred in manure and carrion, and undergo their change in a very few days. Their purpose in nature is to consume various substances which would otherwise taint the atmosphere.

They generally fly in the same manner as a bird, with the back upwards. They have, however, the wonderful faculty of reversing their position, and of flying backwards, as when starting from a window and alighting on the ceiling.

How the buzzing sound is produced by the fly, has given rise to various conjectures. Rennie ascribes it to the action of the air on the edges of the wings at their origin, as with an Æolian harp-string, or to the friction of some internal organ on the roots of the wing nervures.

Next, how does a fly feed? The sole instrument it possesses for eating or drinking is its trunk or sucker—an instrument convenient enough for liquid food. But having no grinders, how does it effect the consumption of solid matter, such as sugar? The microscope has solved the difficulty, and shewn that the fly dissolves its food by a fluid passing through the sucker, and converting the sugar into a sirup. Few flies withstand the severity of winter; but such as do, remain in a dormant state, frequently in haystacks.

The *Blow-flies* are well known. They deposit their eggs on meat; but when the larvæ which are produced from these are about to change into the pupa state, they penetrate into the earth. These flies are the pests of the larder.

Family *Hippoboscidæ* (or Horse-flies).—The young of this family are remarkable for undergoing their states of larva and chrysalis within the abdomen of the parent, and being born as matured pupæ. The Horse-fly (*H. equina*), the type of the family, infests the horse; strebla, the bat; ornithobia and ornithomya are found upon a variety of birds; leptotena, which has only rudimentary wings, inhabits the deer; and the mallophagi, which are destitute of wings, the sheep.

ORDER APTERA (Wingless Insects) includes a variety of creatures, most of which awaken unpleasant associations in our minds.

The family *Pulicidæ* (named from the *Pulex*, or Common Flea) have the rudiments of wings, but, in point of fact, depend for locomotion on the extraordinary elasticity of their legs, enabling them to make an enormous spring. The power of the flea to penetrate the human skin, and feed on the blood, is only too well known.

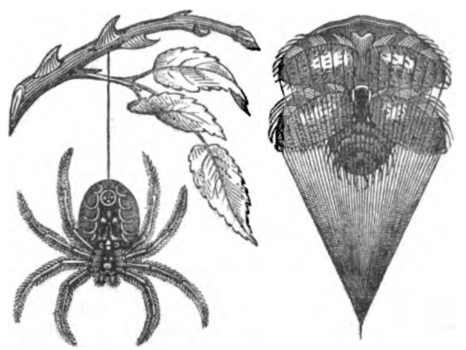
Family *Parasita* are typified by the common Louse, a creature justly regarded with loathing, because it never exists unless in connection with dirty habits. Man, the dog, sheep, and other animals, have each an appropriate parasite of this order. The Parasita are almost entirely destitute of eyes.

Family *Thysanoura* (or Spring-tails) are small insects possessing a forked tail for leaping. The *Podura villosa* is an example. Another is well known under the name of the *Sugar-louse*.

CLASS ARACHNIDA.

The Spiders and their allies, once considered as a branch of the Insecta, are now generally ranked as a distinct class. They may be defined as wingless, articulate animals, with jointed feet; the head confluent with the chest, and the body, consequently, consisting of only two segments. They have eight legs, and smooth or simple eyes. They possess no evident or distinct organ of hearing; yet it cannot be doubted that they have a perception of sound. A very acute sense of touch resides in their tarsi and palpi.

Their instincts are very perfect, and even capable of striking development; and they require the full exercise of these faculties to circumvent their prey—as the latter are instinctively apprehensive of their natural enemies. Many of them weave a net for the purpose of intercepting the flies on which they expect to feed; others, which have not the means of doing this, roam forth or form pitfalls, and exercise their ingenuity in a variety of ways to obtain their provisions. The thread of which the spiders make their nets is a substance similar to the silk of the silk-worm and other caterpillars, but of a much finer quality. It proceeds from reservoirs into which it is secreted in the form of a viscid gum, and issues from the hinder part of the abdomen, where the thread is drawn through little teat-like protuberances.



Spider, with thread-making organ magnified.

Nobody can have taken an early morning-walk, especially towards autumn, without having noticed the lines and webs of the spiders spread on hedge and fields. Spiders are oviparous, and their eggs are contained in a ball generally larger than the body of the parent, which is popularly known as the egg. Spiders undergo no metamorphoses.

ORDER PULMONARIA (*pulmo*, a lung) includes the Arachnidans, which breathe by means of pulmonary sacs or lungs, contained in the under side of the body, and opening externally by stigmata, or small apertures.

Family *Araneidæ* are divided into two sections—Terrestrial and Aquatic. The former, inhabiting the earth, are either suspended in the air or cavities in rocks or trees, or they are affixed to plants, or else they occupy holes in the ground. To this section belongs the *Mygale*, the most powerful insect of the order. When at rest, it covers a space of six or seven inches in diameter. Other species of Mygale burrow in the ground, and go under the name of *Mining Spiders*. They construct in dry situations subterranean cylindrical

galleries, often two feet deep, and so tortuous that the traces of them are lost. These they line with a silken tube, forming at its entrance a movable lid, composed of silk and earth, attached to the silken lining by a sort of hinge. As the spider goes out and in, this door shuts of itself. Thus the creature lives like a robber in a cave, ready at all times to make attack, and comparatively safe from detection.

The Aquatic Araneidæ dwell in the midst of the waters, in a cell filled with air; this consists of finely woven silk, in the form of a diving-bell, sometimes submerged, at others partly above the water, but always forming a dry and comfortable residence. From this their filaments are spread in the water to catch their prey.

Family *Phryneidæ* inhabit the intertropical regions of the Old and New World. Their habits are not well known; but they are much feared in the countries where they live. They are of a large size, and malignant aspect.

Family *Scorpionidæ* (Scorpions) are easily known by their large maxillary palpi, which form a prehensile organ resembling the claw of a lobster. In addition to these powerful instruments, they have, at the extremity of their long tail, a poisonous sting, which they employ with deadly effect. Seizing the little animal with the claws, they strike it with the sting, and then devour it. They are also fond of the eggs of spiders and insects. A small species inhabits this country; but it is between the tropics that the Scorpions attain their greatest development.

ORDER TRACHEARIA (τραχεῖα, the windpipe) includes such spiders as breathe by tracheæ.

Family *Solpugidæ*.—The spiders of this family are usually covered with long hairs or spines, and are said to be venomous. They frequent sandy districts of hot countries. They run with great rapidity, holding up their heads as if to defend themselves. Some minute species of this family, found in moss, are natives of our country.

Family *Phalangidæ* (φάλαγξ, a compact mass).—They are so called from the head, thorax, and abdomen being united. Their mandibles are very strong.

Family *Acaridæ* (Mites).—Arachnidans, which have either a single jointed pincer, representing an antenna, or a suctorious mouth. They are all extremely minute or even microscopic, but often present themselves to our view, running swiftly along damp furniture in dusky situations. They occur everywhere—beneath stones, in moss, under the bark of trees, in flour, and dried provisions; but nowhere are more conspicuous than in the recesses of old cheese, which they will devour to the crust, if not prevented. Others are parasites upon the skin or in the flesh of animals. Of the latter, the Itch insect is a remarkable example. They are naturally much flattened in form, but by suction become swelled out like blown bladders. Many persons consider the cheese acarus or mite a delicious morsel.

PROVINCE FOURTH.

VERTEBRATA.

The last and highest division of the Animal Kingdom is composed of animals in which the leading feature of distinction is the possession of a backbone or vertebral column. This peculiarity of structure is evidently designed, not merely as the central part of a framework giving support to the figure, but as a case for the preservation of a nervous system superior to that of other animals, the skull, which may be considered as an expansion of its upper extremity, containing a large nervous mass, named the brain, while a tube running along the interior of the vertebræ is occupied by the spinal-cord, a continuation, as it were, of the brain, and the trunk, from which nerves branch off to all parts of the body. The general bony fabric, of which the vertebral column is the main or central part, is *internal;* that is, the muscular masses of the body are extended over it—an arrangement, it will be observed, contrary to any in the lower provinces of creation, where the hard and sustaining parts of the frame are always *external.* The skeleton usually comprehends four extremities, serving for progression, and occasionally for prehension or seizing, but subject to many variations, according to the element in which the animal lives, and the nature of its necessities. By virtue of their superior nervous system, the vertebrated animals stand decidedly above other provinces in intelligence. Another notable peculiarity, is their possession of red blood.

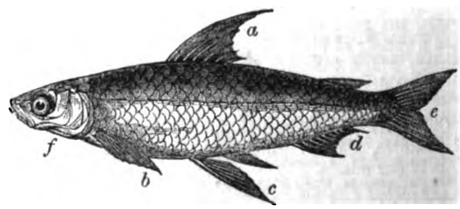
In the Vertebrata, there are four well-marked groups, denominated *classes*, rising in grades above each other, according to the character of their organisation, in this order: 1. Fishes; 2. Reptiles; 3. Birds; 4. Mammalia, or Suck-giving animals. The peculiarities on which the gradation is founded, will be adverted to in the introductory descriptions of the several classes.

CLASS FISHES.

The animals of this class are wholly aquatic, and are the only Vertebrata which, in their adult state, are formed for respiring beneath the surface of the water. They are furnished for this purpose with *branchiæ*, or gills—organs which we have already seen in the humbler provinces of the Animal Kingdom—being composed of a series of delicate filaments, through which the blood circulates, in order to be exposed to a needful chemical change by coming in contact with the air contained in the water. The lungs, by which the same function is performed in the higher vertebrata, do not exist in fishes; but in some a rudiment of this organ is found, in the form of a bag, serviceable in floating the animal, and called the *swimming-bladder*.

In fishes, the heart contains only two cavities; one of which receives the blood which returns from the system, the other propelling it through the gills, from which it is conveyed by the blood-vessels to the body at large. The blood in them, as in reptiles, is cold.

The individual vertebræ in the spinal column of the fish are hollowed on each side, with a bag of lubricating fluid between—an arrangement which gives great suppleness and agility of movement. In one large class, the bones never advance beyond a cartilaginous state. In the fishes generally, the limbs take the form of *fins*, the fore pair as what are called the *pectoral* fins, the hind pair as the *ventral* fins; and these are used rather as steering than as propelling organs. The chief progressive power resides in the vertically formed tail, which the fish uses exactly in the way in which we employ a single oar in sculling along a boat. The surface of the body of fishes is usually covered with scales; and these are sometimes quite bony, and fitted closely together, especially where the internal skeleton is soft. In many species the gills are covered by a corneous plate, styled the *operculum*.



Fish:
a, dorsal fin; *b*, pectoral fin of one side; *c*, ventral fins; *d*, anal fin; *e*, caudal fin, or tail; *f*, operculum.

Fishes are very generally carnivorous, preying much on the weaker of their own kind; but some are herbivorous.

They are nearly all oviparous (egg-producing), and some of them exhibit an amazing degree of productiveness. The cod is reckoned as having a progeny of four millions at a time! The female fish deposits her eggs, or spawn, leaving to the male the duty of afterwards impregnating them.

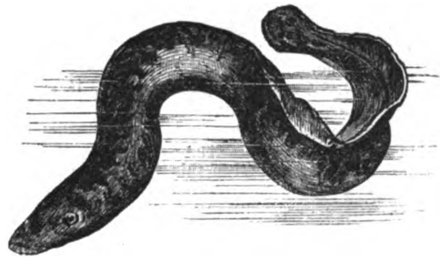
In the preceding representation of a fish, we see, 1*st*, the dorsal, anal, and caudal fins, prolongations of the spine, serviceable in balancing, steering, and progressing; 2*d*, the pectoral and ventral fins, four in number, answering to the four extremities of a quadruped, or the arms and legs of a human being, and likewise useful for motion. In most fishes, the ventral fins are placed far back, in the usual position of hind-legs; but in a few they are fixed far forwards, even anteriorly to the pectoral. These fins are composed of a set of bony or cartilaginous rays, answering to the bones of the hand and foot, and covered with a membrane. The bones representing the limbs are short and hidden under the flesh. Thus the chief movement of the fins is, as it were, at the wrist and ankle-joints. In some species, these fins are absent, and the fish is said to be *apodal*. In other instances, the pectoral fins are enormously developed, like the wings of birds, and even enable the animal to rise out of the water, and for a short time skim over its surface.

The teeth of fishes are chiefly designed to serve as means of seizing prey; they are ordinarily conical in form, sharp at the points, and curved backwards. They are not only placed on the jaws, but also on the tongue, the palate, and other parts of the passage into the stomach. In some species, the jaws and palate are furnished with hard enamelled plates, set together like a pavement, and fitted to bruise and break down the hardest substances capable of affording nourishment. In this way the *sparus* is enabled to browse upon the branching coral, for the sake of the animal matter which its cells protect. Fishes thus furnished were more abundant in the early ages of creation.

The first division of the Fishes is into *Cartilaginous* (gristly) and *Osseous* (bony). It is remarkable that the former alone existed at first and for many ages, and the osseous did not make their appearance till the era of the chalk-formation. The whole class is arranged in nine orders, of which three belong to the *Cartilaginous*, and six to the *Osseous*.

The Cartilaginous Fishes, equivalent to the *Chondropterygii* of Cuvier, are most prominently marked by that character of the skeleton from which they take their name. The different parts of this frame, moreover, which in the osseous fishes are united by distinct joints, here frequently form one continuous piece. This is most remarkable in the head, which is composed of a single piece; in which, however, the principal parts found in the bony fishes may be distinguished by various ridges, furrows, and holes. In respect of the skeleton, this division of the fishes ranks below the other; but, on the other hand, it comprises some of the fishes of greatest intelligence, and while the osseous are all oviparous, many of these are viviparous, bringing forth their young alive.

Order Cyclostomata derive their name from their round mouth, composed of a fleshy lip supported by a cartilaginous ring, and adapted for adhering to prey and drawing nourishment therefrom by suction. In this group of fishes, which is certainly the lowest of the whole class, the spinal column has no distinct division into vertebræ, but is merely a cylindrical membranous tube; the pectoral as well as ventral fins are absent; and the skin is soft and mucous, with scarcely a vestige of scales. This order contains but a single family. The *Lampreys* are the most allied to other fishes in their general organisation; they possess teeth within the ring, and with these they tear the bodies of the animals to which they attach themselves. There is a marine species two or three feet long, and other smaller ones which inhabit rivers. The *Myxine*, or Hag, is destitute of eyes, and is altogether of lower organisation than the lamprey; but



Lamprey.

the species that differs most in its general characters from the rest of the class, is the *Amphioxus*, or Lancelot. This is a very small animal, about an inch long, sometimes found lurking under stones in pools left by the ebbing tide. It is destitute of almost every one of the characters which have been mentioned as peculiar to vertebrated animals, and, nevertheless, can scarcely be classed anywhere else than with this family.

Order Selachii.—A peculiarity of the Cyclostomata, that of having the gills so attached to the skin that the water cannot escape from their intervals except by holes in the surface, is shared by this order; the two being accordingly recognised as *Chondropterygii branchiis fixis*.

This order comprises one family—that of *Sharks* and *Rays*. They are distinguished from other fishes by many peculiarities: in several species, the young are produced alive, the eggs being hatched within the body of the parent; and in others, the eggs are enclosed in a peculiar horny casing, which has often long tendril-like appendages, that coil around and attach them to other bodies. This is the case with the eggs of the common Dog-fish and Skate of our coast, and vulgarly known as *sea-purses*. The Sharks much resemble ordinary fishes in their form, having the gill-openings on the sides of the neck, and the eyes on the sides of the head, in both of which respects the Rays differ from them.

The White Shark is the most celebrated species of the tribe, being, from its size and voracity, the terror of mariners in the seas it inhabits. It frequents warm latitudes, but has occasionally visited the British shores. It has been known to attain a length of thirty feet, and the opening of the jaws in the largest individuals is sufficient to admit with ease the body of a man. The mouth is placed on the under surface of the head, from which circumstance the fish cannot bite whilst in the act of swimming forwards, so that a dexterous person has been known to defend himself from its attack. The teeth are triangular and lancet-shaped, with acute points and edges, and form several rows; they are not fixed in the jaw itself, but in a muscular membrane, by which they are erected and made to project when in use, lying flat in the intervals. As the foremost are torn away, they are replaced with others, which are brought up from the rows behind. So acute and strong are these teeth, that they are used by many savage nations as the armature of their weapons. The shark, possessed of this powerful apparatus for attack, and having a very hard and rough skin for defence, with very great muscular power, is a match for almost any of the inhabitants of the ocean. The Blue Shark, which frequents the Mediterranean, is not unfrequently a source of great trouble to the fishermen of our coasts, on account of the injury which it does to their nets, and the loss of the fish they contain. The Fox Shark, or Thresher, is another of the second-rate species which occasionally makes its appearance on British coasts; it is distinguished by the size of its tail, and the use it

makes of it as a weapon, both of offence and defence—whence its name.

A remarkable genus allied to the sharks is the *Zygæna*, or Hammer-headed Shark, so named from the projection of the head at each side in the form of a double-headed hammer, with an eye in the middle of each extremity. The *Pristis*, or Saw-fish, is another interesting genus. Its general form and character are like those of the sharks, but the snout is extended like the blade of a sword, with strong and cutting tooth-like spines on both edges. With this formidable weapon, the fish, which sometimes attains the length of from twelve to fifteen feet, will attack the largest whales, and inflict dreadful wounds. To the shark tribe also belongs the *Angel Fish* of our own coasts, which commonly grows to the length of seven or eight feet. Its appearance much belies its name, being, according to our ideas of beauty, one of the ugliest of fishes; but its flesh is by no means unpalatable.

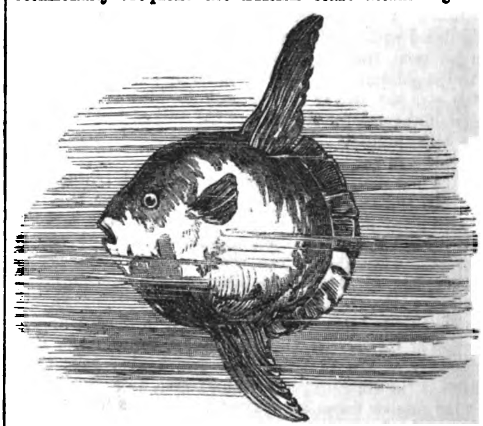
The *Rays* are less numerous than the sharks, and abound rather in temperate than in tropical seas. They are characterised by the extreme horizontal flattening of the body. The two sides are spread out horizontally, and unite with the expanded and fleshy pectoral fins to form one continuous surface. The eyes are placed on the back or upper surface, whilst the mouth, nostrils, and gill-openings, are below. To this group belong the Rays and Skates, Thornbacks, and other species; but the most interesting of all is the Torpedo, or Electric Ray, sometimes found on the Channel coast of England, but more abundantly in the Mediterranean. It possesses an electric apparatus, disposed in the space between the pectorals and the head and gills, and by which it can give a smart shock to any animal it touches. The flesh of the Rays is wholesome, and that of most species agreeable as food. The skin of some of them is employed in the arts for polishing, and from that of others shagreen is made.

Order Chondropterygii Branchiis Liberis, deriving their appellation from having the gills attached by one edge only, and hanging in fringes, as in the osseous fishes, form but one family—the *Sturiones*, or Sturgeon tribe. They are chiefly river-fish, and from their large size, vast numbers, and the quantity of food and other important products they afford, are extremely valuable to man. The common sturgeon of the British shores is about six feet long, and its flesh is somewhat like veal. The rivers falling into the Black and Caspian Seas, however, produce several other species, of which the largest not unfrequently attains the length of fifteen feet, one individual being recorded as having weighed 3000 pounds. The roe of the sturgeon furnishes the caviare, so much esteemed in Russia; and its air-bladder furnishes isinglass. The *Chimæra*—of which a northern species, known as the king of the herrings, often accompanies herring-shoals—is a genus intermediate between the sturgeon and the sharks, having the gills fixed, but having only one external gill-opening, covered by the rudiment of an operculum; this leads, however, to five interior passages.

The Osseous Fishes are classified by Cuvier with a reference chiefly to characters of the fins and gills. Three orders are denominated *Malacopterygii*, as having the fin-rays soft, each bearing an additional designation according to the position or absence of the ventral fins. One order is designated as *Acanthopterygii*, from having the fin-rays spiny. Two other orders are distinguished by other peculiarities—*Lophobranchii*, or Tuft-gilled, and *Plectognathi*, or Jaw-soldered.

Order Plectognathi approaches the Cartiligines in many points of organisation; principally, however, in the slow ossification of the skeleton, and the imperfect structure of the mouth. They derive their name from the union of the upper jaw to the skull; so that its motion is obtained, not from a distinct joint, but by the mere flexibility of the half-ossified cartilages. The gill-lid is concealed under the thick skin, with only a small opening; the ribs are scarcely developed; and there are no true ventral fins. This order contains two families.

The *Gymnodontes* (Naked-toothed Fishes) are distinguished by having the jaws covered with a substance resembling ivory, arranged in small plates—which are reproduced as soon as destroyed by use—and really representing united teeth. They live on crustacea and sea-weed, and their flesh is not palatable. Some species are reputed to be poisonous, at least at particular seasons. The most remarkable species of this family are the spinous globe-fishes, *Diodon* and *Tetraodon*—their technical names being derived from the apparent division of their jaws into two and four tooth-like pieces respectively—which have the power of blowing themselves up like balloons, by filling with air a large sac which nearly surrounds the abdomen. When thus inflated, they roll over with the belly upwards, and lose all power of directing their course; but they are remarkably defended by spines over their whole surface, which are erected as they are inflated. They are mostly inhabitants of warm seas, but a specimen is occasionally drifted to our coasts. The *Sun-fish* has a body of somewhat similar form, but incapable of inflation; from the shortness of the tail, it looks like the anterior half of a fish cut in two in the middle. Some species which occasionally frequent the British coast attain a great



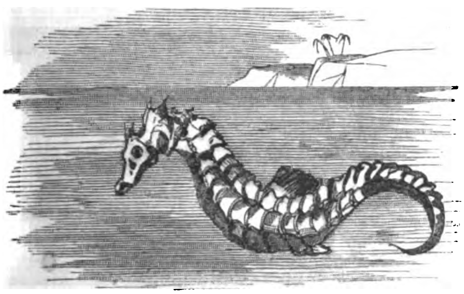
Sun-fish.

size, having been known to weigh 300 pounds, while others are much larger.

The second family, *Sclerodermi*, contains fishes which are remarkable for their very hard and granulated skins. They have a prolonged muzzle, with distinct teeth. Their skin is covered with scales in some species, and in others very rough, like a file, whence they are commonly termed *file-fishes*. They are principally inhabitants of warm seas, living near rocks, or on the surface of the water, their brilliant colours sparkling in the sunshine. The *Balistes*, or File-fishes, are generally remarkable for the appendages of various kinds attached to the surface of the body. One of the most curious species in this respect is the *B. pencilligerus*, whose body is covered with little branched stalks resembling aquatic plants. Not improbably, these may serve as lures for the animals upon which this fish preys, its body lying concealed among the rocks, whilst these curious little prolongations are gently agitated by the water.

Order Lophobranchii is a very small one, containing but one family, of which the genera are few. Their appearance is very peculiar. The tufted gills are covered

by a large operculum; but this is bound down by membranes on all sides, so that there is only one small hole for the water to escape. The body is covered, not with small scales, but with shields or plates, which often give it an angular form. In general, they are of small size, and almost without flesh. The *Syngnathus* possesses a long tubular snout. It is peculiar for the protection it affords to its young, which resembles that provided in the marsupial mammalia. The eggs are conveyed into a sort of pouch under the body of the male, and are hatched there, the young fry afterwards finding their way out. Some of these are found in the British seas; as are also the *Hippocampi*, commonly called *sea-horses*,

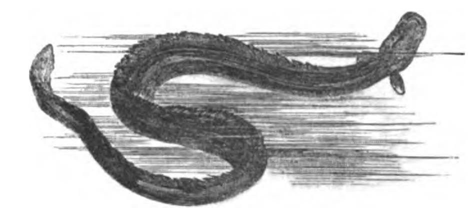


Sea-horse.

from the resemblance of the upper part of the body (especially when the dead specimen bends in drying) to the head and neck of a horse in miniature. The tail is prehensile, and they climb or hold on to the stalks of marine plants by its means.

ORDER MALACOPTERYGII APODA (Soft-finned Fishes, destitute of ventral fins) form but one natural family—the *Murænidæ*, or Eel tribe. They are all lengthened in form, have the spine extremely flexible, the skin thick and soft, and the scales almost invisible. Many of them inhabit rivers, whilst others are exclusively marine. The eel is, strictly speaking, a fresh-water fish; but when living in rivers, or other collections of water communicating with the sea, it migrates towards the ocean in the autumn. During the winter, they bury themselves in the mud; and in the spring, those which have migrated usually return up the rivers, together with the young fry produced from the spawn, the number of which is enormous. Like trout, eels are much affected in appearance and quality by the waters they inhabit. They are very voracious, especially during the spring and summer months, not only devouring insects and small fry—on which last account they are often excluded from fish-ponds—but also attacking larger fish. As is well known, the eel can live for a little while out of the water, and is often found wriggling its way by night among damp grass, in pursuit of frogs, slugs, and other prey. It is enabled to do so by the smallness of the gill apertures, keeping the breathing organ moist—the only requisite, it appears, for prolonging the life of a fish out of its ordinary element. Occasionally they eat vegetable substances. By means of a long and capacious air-bladder, eels rise to various elevations in the water with great ease.

The Conger is a marine eel, frequenting the European seas; it is one of the largest of the family, being from four to six feet long, and as thick as a man's leg. The *Muræna* is destitute of pectorals as well as ventrals: one species of it was much esteemed by the ancients, who carefully fed it in ponds; and it is recorded that offending slaves were sometimes flung alive into the ponds for their supply. The *Gymnotus*, or Electric Eel, is a native of the South American rivers. It attains the length of five or six feet, and communicates shocks so powerful that men and horses have been stunned by them. This power seems voluntary, and can be sent in a particular direction, or even through the water, the fish in which are killed or stunned by its shocks. By giving these the animal is greatly exhausted, and requires rest and



Electric Eel.

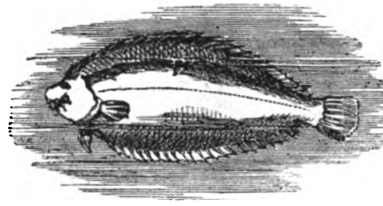
nourishment before it can renew them. The electric organ extends along the under side of the tail, occupying about half its thickness. It consists of parallel layers of membrane, joined by numerous transverse folds, so that a number of canals or cells are formed which are filled with gelatinous matter. The apparatus is largely supplied with nerves. Some species of this family, which is commonly known under the name of *Anguilliform*, or Eel-like Fishes, approach very closely to the lower reptiles in the structure of the air-bladder or lung; and in these the external opening of the gills is usually very small.

ORDER MALACOPTERYGII SUB-BRACHIATA derive their subordinate name from having the ventral fins brought forwards beneath, or even in advance of the pectoral. They form three families.

Family *Gadidæ* (the Cod tribe) are easily known by the softness of all their fins, and by having the ventrals inserted under the throat, and pointed. The Cod is nearly the largest of the family, but is usually surpassed by the ling, which is commonly from three to four feet long: both these are especially valuable for their palatableness when salted. The Haddock is a smaller species, nearly allied to the cod; for eating in the fresh state it is perhaps the most delicate of the whole family. Many other species are useful to man, occurring in large numbers in particular localities. Such are the Whiting, the Coal-fish, the Pollock, the Haak (of which some species frequent high southern latitudes), the Burbot, or Eel-pout (which ascends rivers), the Rockling, and many others. Besides their use as food, these fish are valuable on account of the oil obtained from their large livers, which is very serviceable in the arts and in medicine.

The second family is that of *Pleuronectidæ* (the Flat-fish, or Flounder tribe).—The form of these fish is peculiar, not only for the extreme flattening of the body, but for its deficiency in symmetry. The two flat surfaces —one of which, in the ordinary position of the fish during life, is above, and the other below—are in reality the two *sides* of the fish, differing in several important respects. Both the eyes are placed on the upper side; and its colour is usually much deeper than the other. The body, from the head backwards, partakes a little of the same peculiarity. The two sides of the mouth are not equal, and the pectoral fins rarely so. On the other hand, the dorsal fin, which runs along one of the lateral edges, corresponds with the anal, which occupies the other, and with which the ventrals are sometimes united; so that, when we look at the fish in its usual position, its body appears more symmetrical than it really is. These fishes are destitute of air-bladders, and they frequent the bottom of the sea, from which they seldom rise. The colour of their upper surface usually corresponds closely with that of the ground on which they lie, and thus they escape the observation of their enemies, and are unnoticed by the small fishes on which they prey. Individuals are occasionally found, however, in which both sides are alike; these are called *doubles:* it is usually the dark side which is doubled. The fishes of this family are found along the shores of almost all countries, and are, generally speaking, wholesome and

agreeable as food. The form and aspect of the different species exhibit little variation. The Flounder, Turbot, Brill, Plaice, Dab, and Sole are the chief species of our



Sole.

own coasts. The Halibut is a very large species, sometimes attaining the length of six or seven feet—frequently taken in the British seas. Other species inhabit the Mediterranean.

The *Discoboli*, so named from having their ventral fins formed into a sucker or disk, are the last family of this order. By this curious provision, the fish have the power of attaching themselves to rocks and other hard substances, and thus to remain and find their food in situations where every other species would be swept away by the current of water. Several species are found on the British coasts, but they are mostly small; the most considerable is the Lump-fish, which is occasionally eaten. The *Echeneis remora*, or common Sucking-fish, is placed under this family, but probably ought to constitute a distinct group, since its disk is not formed by the ventral fins, but by a series of thin and movable cartilaginous plates fixed to the head, by means of which the animal can attach itself to any kind of surface. It seems to prefer bodies in motion; and is not unfrequently found adhering to larger fish, and to the bottoms of vessels, whose course it was once absurdly believed capable of arresting. It is abundant in the Mediterranean.

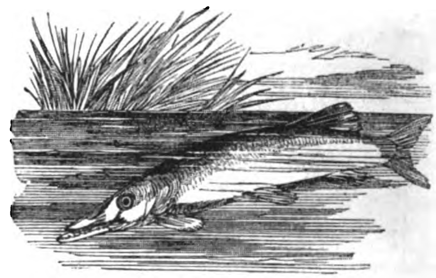
ORDER MALACOPTERYGII ABDOMINALES consists of soft-finned fishes, having the ventrals attached to the abdomen, behind the pectorals. It is a very numerous order, including the greater number of the fresh-water fishes. There are five families.

Family *Cyprinidæ* (Carp tribe) are all fresh-water

Carp.

fishes. They have the mouth shallow, the jaws feeble, and very often without teeth; but the pharynx is strongly toothed. They are among the least carnivorous of fishes, feeding chiefly on seeds, the roots of plants, and decomposing vegetable matter. The common Carp is imported into England from the warmer parts of Europe; it thrives better in ponds or lakes than in rivers; it feeds on insects and worms, as well as on vegetables; and it is very tenacious of life, so that it is easily transported from place to place. The Barbel is an allied species of considerable size, sometimes growing to the length of three feet. It frequents the sluggish parts of the Thames and its tributaries, and is said to plough up the mud with its nose, which, setting various minute animals adrift in the water, attracts the small fishes on which it feeds. The Cobitis or Loche is another British species, which is interesting in some of its habits. It inhabits the mud of stagnant waters, and can subsist a long time after the water has been dried up or covered with ice. The Anableps, a genus allied to the cobitis, has a remarkable peculiarity of structure in the eye, each cornea and iris being divided by transverse bands, so as to give the fish the appearance of having four eyes. The object of this conformation is unknown. The fish inhabits the rivers of Guiana.

The *Esocidæ* (Pike tribe), the most voracious of the



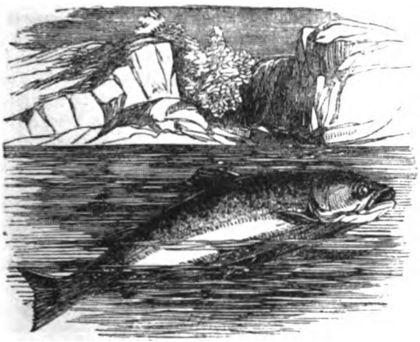
Pike.

fresh-water fishes, are distinguished by the absence of fatty matter in the dorsal fin (which exists in the salmon tribe), and by the position of this opposite to the anal fin. The Pike is very destructive to the smaller fishes in the ponds and rivers in which it exists, and occasionally attains a considerable size, weighing sometimes thirty or forty pounds. The *Gar-fish*, or Sea-pike, is an allied species, frequenting the British shores, and stretching into the Arctic regions. Some of this kind have been known to attain the length of eight feet, and to bite very severely; hence they may be considered as the sharks of northern seas. The *Mackerel-pike*, or *Saury*, is another British fish of this family; it is gregarious in its habits, and is followed and preyed upon by porpoises, tunnies, and other large fish. To this family belongs the most common of the flying-fish, though it is not the only one which deserves the title.

The *Siluridæ* are distinguished from all the rest of the order by the want of true scales; having only a naked skin, or large bony plates. The fishes of the genus *Silurus* inhabit the rivers of warm countries; they have a strong spine in front of the dorsal fin, which can be laid flat on the shoulder, or perpendicularly erected so as to become a formidable weapon; and the ragged wounds inflicted by it are reputed (but probably erroneously) to be poisonous. One species, belonging to the sub-genus *Malapterurus*, an inhabitant of the Nile and of the rivers of Central Africa, has electric properties, similar to those of the torpedo and gymnotus.

The *Salmonidæ* (Salmons and Trouts) are very extensively, indeed almost universally, diffused over the globe; some of them being confined to fresh water, and others passing a part of their lives in the sea, but resorting to rivers to deposit their eggs. They are distinguished by the fatty deposition in the dorsal fin, from part of which the spines often disappear. All of this family are clouded with dusky patches when young, and many remain permanently spotted. The flesh of most of them is esteemed as food. The Salmon inhabits the seas of comparatively cold regions, ascending the rivers for the purpose of spawning, at seasons varying with the climate. The efforts which they make to overcome difficulties in the ascent are very great: they will not only swim against powerful streams, but will leap up cascades of considerable elevation, and find their way to the brooks

and small lakes of lofty mountains. After this operation is accomplished, they return to the sea, followed by the young fish. These, in their turn, ascend the rivers for the same purpose, and are understood to resort to those in which they were produced. The Trout appears to vary much in size and colour, according to the climate and other conditions of its residence, so that it is difficult to distinguish species from mere varieties. The growth of this fish is wonderfully rapid, individuals previously marked having been found, when recaptured three weeks



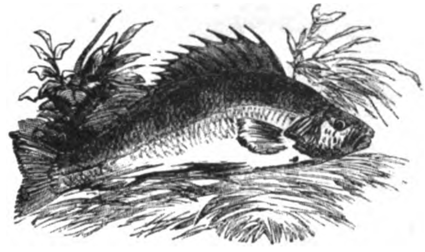
Salmon.

afterwards, to have grown several pounds heavier. Besides these may be mentioned, as belonging to the same family, the *Smelt*, which is sometimes found abundantly, but locally, in the estuaries of British rivers; and the *Capelin*, which is employed on the shores of Newfoundland as a bait for cod, and is sometimes taken in such quantities as to serve as manure for the land.

The *Clupeidæ* (Herring tribe) is one of the most important families in the whole class, for the amount of food it supplies to man. The fishes belonging to it resemble the Salmonidæ in many characters, but differ in having no fatty matter in the dorsal fin. They chiefly inhabit the seas of the temperate zone. The Herring, which periodically visits our shores in such immense shoals, was formerly supposed to migrate from the Arctic seas; but this is now ascertained to be a mistake, the fish being almost unknown there, and often appearing on the southern coast of Britain before the northern. The fact is rather that the herring, like the mackerel and many other fish, usually lives in the open ocean, and resorts to the nearest coast to deposit its spawn. There are many well-known species, differing but little from the herring, which frequent separate localities. Thus, the *Pilchard* is caught especially on the coast of Cornwall, and other shores to the southward of those on which the herring most abounds. The *Sardine* is taken on the west coast of France, and in the Mediterranean, where the herring never appears. The *Sprat, Whitebait, Shad*, and other British species, belong to the same family, as does also the *Anchovy*, abundant in the Mediterranean, and well known for its rich and peculiar flavour. Other species inhabit the American, African, and Indian seas and rivers, but are less abundant than those already mentioned.

Order Acanthopterygii (Spiny-finned Fishes) are divided by Cuvier into fifteen families.

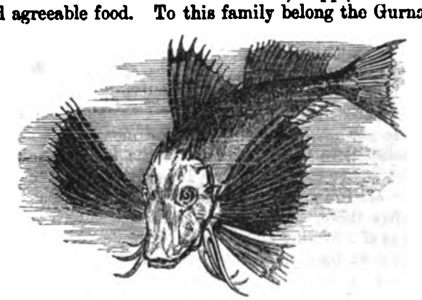
Percidæ (the Perch tribe).—These are very numerous in the waters of all warm climates, some species inhabiting the rivers, and others the open sea. Their bodies are oblong, and covered with hard or rough scales; and the gill-covers are toothed at the margin. They are mostly *thoracic*, or have the ventral fins under the pectoral. Some, however, are *jugular*—that is, have the ventral fins placed upon the throat, further forwards than the pectorals; and some are *abdominal*. Their teeth are very minute, and set close together in numerous rows. The flesh is, in general, agreeable and wholesome. This family, of which some species are found in almost all the rivers in the world, includes all the fish known as perches, and a large number of marine



Perch.

fishes used as food on different shores. Some of the most remarkable are—the *Trachinus*, or Weaver, which has a very prolonged and sharp dorsal spine, capable of inflicting a severe injury, and which fishermen believe, but erroneously, to have poisonous properties; the *Uranoscopus*, or Star-gazer—so called from the position of the eyes upon the top of a nearly cubical head—which lies concealed in the mud, and attracts its prey by a filament protruding from its mouth, and serving as a bait to small fishes; the *Polynemus* (many fillets), whose pectoral fins are prolonged on each side into threads twice as long as the body, and of which a species inhabiting the Ganges, termed the Mango-fish, is esteemed the most delicious in India; the *Sphyræna*, or Sea-pike, to be distinguished from the common pike, of which one tropical species, the *Barracuda*, is much dreaded for its size and voracity; the *Red Mullets*, or, more properly, *Surmullets*, of the British seas; and many others.

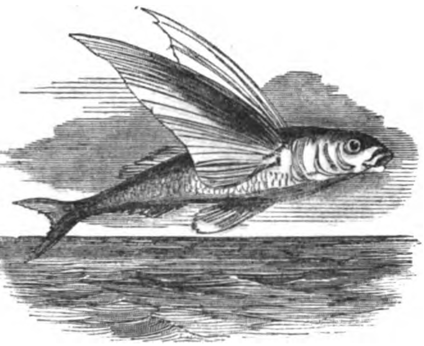
Triglidæ (the Gurnard tribe).—These bear a general resemblance to the perches, but have the head peculiarly armed with spines or hard scaly plates. In several species the pectoral fins are very much extended; but in none, except the flying-fish, are they sufficiently powerful to raise the animal out of the water. Many species of this tribe are found in the temperate seas, which, though inferior in flavour to the surmullets, supply wholesome and agreeable food. To this family belong the Gurnards



Gurnard.

and Sticklebacks of our own coast; the *Scorpæna*, a gregarious fish, living among the rocks; the *Sebastes*, or Norway haddock, rather a large species, the spines of which are used by the Greenlanders as needles; and a large number of others. The most interesting of all is the *Dactylopterus*, or Flying-fish. This has a kind of supplementary pectoral fin on each side, formed of a membrane stretched over finger-like processes, which in the gurnards are unconnected. By the impulse of these on the surface of the water, the flying-fish can rise several feet into the air, and suspend themselves above the surface for a few seconds, often skimming lightly over it for a considerable distance. They are gregarious; and it is when a shoal of them is chased by the Coryphæna

—commonly, but erroneously, termed *dolphin*—or some similar enemy, that the most remarkable leaps are taken.



Flying-fish.

They sometimes fall victims to predaceous birds, and not unfrequently fall upon the deck of vessels that happen to be passing amongst them. The finger-like processes are usually prolonged beyond the fins, and appear to possess an amount of sensibility unusual in such parts.

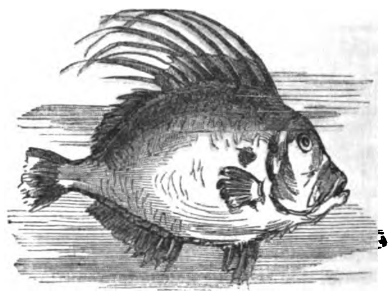
The *Sciænidæ* (Maigre family) have a general resemblance to the perches, but differ from them in the absence of teeth from the palate, and some other particulars. They principally belong to tropical seas, a few inhabiting the Mediterranean.

The *Sparidæ* (Sea-bream tribe) resemble the last in general form, but have no spines on the gill-covers. Some of these, including the genus Sparus, already mentioned as grinding down the stony corals, have the sides of the jaws covered with round flat teeth, resembling a pavement. Others have teeth with cutting edges.

Another small family, *Menidæ*, differs from the last chiefly in the great extensibility of the upper jaw.

The next family, *Squamipennes*, is so named because the soft and even the spinous parts of their dorsal fins are so covered with scales as not to be distinguished from the rest of their bodies. The most interesting genus is the *Chætodon*, of which several species, remarkable for the beauty of their colours, abound in tropical seas. One of these, the *C. rostratus*, which has a very prolonged snout, has the faculty of shooting insects with drops of water projected from the mouth, and it then seizes them as they fall. This power is the more extraordinary, as, according to the laws of the refraction of light, the place of the insect will appear to the fish different from the reality—the rays passing from a rarer to a denser medium; and the drop must not, therefore, be projected in the line in which the insect *appears* to be, but somewhat below it. This little fish, which is a native of India, is often kept in glass-vases by the residents there, as gold-fish are in this country, for the purpose of affording amusement by its dexterity.

The next family, *Scomberidæ* (the Mackerel tribe) is one of very great importance to man. It comprises a large number of genera, a vast collection of species, and numberless individuals. The aspect of the common Mackerel, with its spindle-shaped, beautifully coloured, smooth, and small-scaled body, is well known. It very rapidly dies out of water, and soon becomes tainted. The Mackerel has been supposed to be a migratory fish, on account of its appearing on our shores in immense shoals at particular epochs. But it may be caught all the year round on our coasts, which shews that it does not wholly desert them, as is done by the really migrating tribes. The fact is, that it passes most of the year in the open sea, and that its object in approaching the shore is to deposit its spawn; after which, those that have escaped being entrapped by the ingenuity of man, return to their former quarters. The extent and importance of the mackerel-fishery of Britain, especially in the south and east, are well known. The Tunny is an allied species attaining a much greater size, and also valuable as an article of food. It frequents the Mediterranean, and is occasionally seen on our own shores. It sometimes attains the length of fifteen or even eighteen feet. To this order belongs also the *Xiphias*, or Sword-fish, distinguished by its long pointed beak. This is a most powerful offensive weapon, and with it this fish attacks the largest inhabitants of the ocean. By its high dorsal fin and expanded tail, it is able to impel itself forwards with great force; and when attacking a large animal, it makes a violent dart against it, quite transfixing it with its sword. It has been known in this manner to drive its beak into the timbers of a ship, and, not being able to withdraw it, to break it off and leave it. The sword-fish abounds in the Mediterranean, but is less frequent in the Atlantic. It is very palatable as food, and often attains the length of fifteen feet. The *Dory*, of which



Dory.

one species is highly prized by epicures, is another fish of the same family. It is remarkable for the filamentary prolongations from its dorsal fins. And, lastly, may be mentioned the *Coryphæna*, commonly known as the Dolphin. This is a large and splendidly coloured fish, which darts through the water like a radiant meteor, exhibiting an extraordinary play of colours when brilliantly illuminated. It has long been celebrated for its change of colour when dying; a peculiarity which belongs to many other kinds of fish. It swims with great rapidity, and is very voracious, committing great havoc among the flying-fish and others of like size. The influence of light on the colour of animals is remarkably shewn in the far superior brightness of the Indian Scomberidæ, when contrasted with the blackish hue of those of the northern seas.

The family of *Tænidæ* (Ribbon-shaped Fishes) is a small one allied to the Scomberidæ, differing chiefly from it in the remarkable lateral flattening of the body. Few species are known on our shores; one of the largest, *Lepidopus argyreus*, the Scabbard-fish, occasionally appears on these coasts; it is about five feet long, swims with extreme rapidity, and often with the head above water. Allied to this is the *Trichiurus*, some Indian species of which have been said to possess electric properties; but this is doubtful.

The *Theutyes* (Lancet-fish tribe) are another small family allied to the mackerels, but are peculiar for their cutting spines on each side of the tail, and a horizontal spine before the dorsal fin. They have only a single row of teeth, and feed chiefly on marine plants. Their powerful lancet-shaped spines are used very dexterously as weapons of defence; and in this respect may be compared to the horns of the Ruminantia.

The fishes of the tenth family, *Pharyngina labyrinthuformæ*, are characterised by a very peculiar structure, from which they derive their designation. The membranes of the pharynx, or back of the mouth, are divided into small irregular leaves, containing cells among them, which the fish can at pleasure fill with water; and by ejecting a portion of this water the gills are moistened, thus enabling it to continue respiration out of its proper

element. By means of this apparatus, which resembles that possessed by the land-crabs, these fishes are enabled to quit the pool or rivulet which constitutes their usual element, and move to a considerable distance over land. Such a provision is especially desirable in tropical climates, where shallow lakes are often dried up by a continued drought, and their inhabitants must perish if not enabled to migrate. The people of India, often witnessing the appearance of these fishes where they had no previous existence, believe that they fall from heaven. Some of them are able not only to traverse plain grounds, but can climb steep banks, or even trees, in the course of their journeys. The most curious is the *Anabas*, commonly known as the Climbing-perch of Tranquebar, which climbs bushes and trees in search of its prey.

The *Mugilidæ* (Mullet tribe) are lengthened and often nearly cylindrical fishes, with a somewhat projecting snout, and a very small mouth placed beneath it. They are gregarious in their habits, frequenting the mouths of rivers in large troops, and constantly leaping up out of the water. There are several species found in European seas, which are much esteemed from their rare delicacy. That best known on the British coast is the *Mugil chelo*, or Thick-lipped Gray Mullet, sometimes called the Sea-woodcock. The fishes of this family feed in part upon crabs and other small crustacea.

The members of the family *Gobiodæ* (or Goby tribe) are known by the thinness and flexibility of their dorsal spines. Many of them are remarkable for producing their young alive, the eggs being hatched within the body of the parent. This is the case with the Blenny, of which several species frequent the British shores, living in small troops among the rocks. They are remarkably tenacious of life, and are capable of being kept a good many days in moist grass or moss, but they are of little value as an article of food. One of the most interesting species of this family is the *Anarrichas lupus*, or Sea-wolf. It inhabits the northern seas, and is often met with on our shores, attaining the length of six or seven feet. It is very formidable in aspect, and the size of its teeth, with the colours and peculiar physiognomy of its head, remind the observer of the carnivorous mammalia. Its manners accord with its aspect, for it is remarkably strong, very active, and equally ready to defend itself or to attack an enemy. It often enters the fishermen's nets, for the purpose of plundering them of the entangled fish; and when the fishermen attack it, and it cannot escape, it fights like a lion. The Arctic seas appear to be its appropriate home, and there it attains a larger size than further south; it is very valuable to the Icelanders, who salt its flesh for food, and employ its skin as shagreen. The true Gobies have the ventral fins placed far forwards, and united at their bases; they are chiefly remarkable for the *nest* which they construct among the sea-weed for the protection of their young. They prefer a clayey bottom, in which they excavate canals, and in these they pass the winter.

The next family, *Pectorales pedunculati*, derives its name from the peculiar structure of the pectoral fins, which have a kind of wrist formed by the elongation of the bones to which they are attached. This conformation gives these fishes a very strange appearance, and enables them to leap suddenly from the water in pursuit of their prey, and even to leap over the sand. In many of them the skeleton is semi-cartilaginous. One of the most curious is the *Lophius*, or Fishing-frog, of the British seas, which is met with chiefly on muddy shores. It derives its name in part from its wide gaping mouth, and in part from the peculiar manner in which it angles for its prey. There are some curious appendages to its head, which terminate in long, round, and rather brilliant filaments, having a resemblance to worms. The animal lurks in the mud, and puts these appendages in vibration; they are mistaken for worms by small fishes, which they attract, and these are gulped down the capacious maw of the lophius. To such an extent is this voracity carried, that the *angler* (as it is sometimes called) is often an article of value for the fish which it has in its stomach, although its own flesh is but little worth! There is an allied genus, the *Chironectes*, a species of which abounds on the north coast of Australia. When the tide ebbs far back in the dry season, these frog-fishes are so abundant, and capable of taking such vigorous leaps, that persons visiting these places have mistaken them at first sight for birds. The fishes of this genus can inflate their large stomachs with air, in the manner of the tetraodons.

The *Labridæ* (Wrasse, or Rock-fish tribe) are easily known by the thickness and fleshiness of their lips, whence their name. Those of the genus *Labrus* are known on the British shores by the name of *old wives;* some of them vary considerably in colour. They frequent deep pools among the rocks, hiding themselves in sea-weed, and feeding mostly upon crustacea. This family contains a large number of species, chiefly inhabiting tropical seas, and remarkable for the beauty of their colours, but they are usually of small or moderate size; their habits are little known, and they are of but slight direct importance to man. Some of them have received the name of *parrot-fishes*, on account of the brilliancy of their markings and the form of their jaws.

The last family of the Acanthopterygii consists of the *Fistularidæ* (Pipe-mouthed Fishes), at once recognised by the very prolonged muzzle. The body, too, in some species is long and cylindrical, whilst in others it is oval and compressed. They are chiefly found in warm latitudes; but one species, *Centriscus scolopax*, Sea-snipe, Sea-trumpet, or Bellows-fish, is occasionally found on the Cornish coast, as a straggler from the Mediterranean.

CLASS REPTILES.

The class of vertebrated animals next above fishes is distinguished by a name expressing *creeping habits* (*repo*, I creep). Like fishes, the animals of this class are oviparous, or produced by eggs, and many of them are covered with plates and scales. They are also, like fishes, cold blooded. They are superior, however, to fishes, in having lungs, and breathing the atmosphere. While the fish possesses a heart of only *two* cavities, that of the reptile consists of *three*, which may be considered as, in one sense, an imperfect form of the organ; and the consequence is, that only a portion of the blood, on returning from the veins, is propelled through the lungs, the greater part passing again into the circulation without being aërated. Hence it is that the blood is cold, and the digestive powers sluggish and weak. The vitality of the reptile may be said to be low, and it is not surprising that many of them are capable, under a low temperature, of falling into a state of torpor, during which the whole of the animal functions are suspended.

There are differences among naturalists as to the classification of Reptiles; but latterly the tendency has been to consider the Tortoise, the Lizard, the Serpent, and the Frog as the four leading types; and, accordingly, the whole may be ranked in four orders—*Chelonia*, *Sauria*, *Ophidia*, and *Batrachia*.

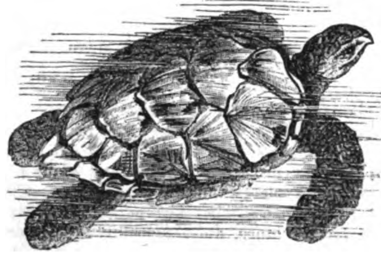
Order Chelonia are distinguished by a peculiar form of the skeleton, having evidently in view the protection of the animal. In typical species, the ribs are expanded so as to form but one bony plate, having no flesh outside, but covered with horny plates, secreted from the skin like hair or nails; the breastbone being similarly expanded into a plate, covering the whole of the lower surface, and joining the edges of the upper plate; so that the animal may be said to be sheltered in a box formed of its bones. Within this box, the upper plate of which is named the *carapace*, and the lower the *plastron*, the animal can even withdraw its head and feet, and thus set most enemies at defiance. When it is

observed that the Chelonia are in general without teeth, claws, or other sharp instruments, and are for the most part herbivorous and of gentle dispositions, it seems not inappropriate that they should be provided with such a means of defence.

In the Chelonia, the jaws are covered with a horny substance, resembling that of the bills of birds; but their surfaces are usually rounded, so as to be more adapted to bruise than to bite. In those designed to live in the water, the extremities take the form of paddles.

The family *Chelonidæ* (Turtles) are designed for a sea-life, feeding chiefly on marine-plants, and only coming on land to deposit their eggs, which they do thrice a year, laying about a hundred at a time. They are generally large animals, sometimes exceeding five feet in length, and 800 pounds in weight. The bones and plates are not so closely joined as in land-tortoises; consequently, their bodies possess a certain degree of flexibility. The *Chelone midas* (Green, or Edible Turtle) is noted for the delicious food which it yields. Animals of this species may be seen in the tropical seas of America, browsing in large flocks on the plants growing on the bottom, only ascending to the surface now and then to breathe. They migrate hundreds of leagues to lonely shores, where there are loose sands fitted to hatch their eggs. Ascension Island, in the South Atlantic Ocean, is noted as one of their favourite retreats.

The *Chelone imbricata* (Hawk's-bill Turtle) is a smaller species, having a horny and pointed muzzle,



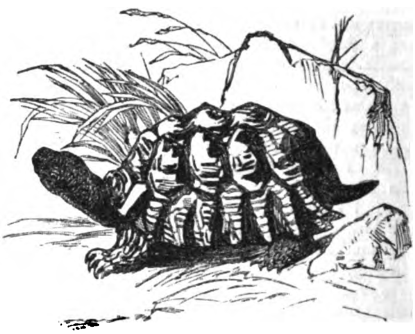
The Hawk's-bill Turtle.

fitted to cut as well as bruise. It is remarkable on account of the horny plates covering its carapace, which, being thicker and stronger than usual, and beautifully coloured, furnishes a material for combs and other useful articles. About twelve pounds of *tortoise-shell*, as the substance is called, is yielded by each full-grown animal. These plates do not join at the edges, like those of land-tortoises, but overlap each other, like the scales of other reptiles.

The *Chelone caretta* (Loggerhead Turtle) has a strong mouth with sharp jaws, and feeds upon various marine animals, as well as plants. The carapace is covered, not by plates, but by a thick leathery skin. This animal (called also Sphargis) inhabits the Mediterranean, as well as the Atlantic and Pacific Oceans.

The family *Emydæ* (Fresh-water Turtles, or Mud Tortoises) are comparatively small animals, distinguished by the form of their feet, which end in toes furnished with claws, but nevertheless, being webbed, are useful for swimming. They inhabit the rivers of the south and east of Europe. To this group belongs the *Snapping Turtle* of America, a comparatively destructive and powerful animal, possessed of sharp claws and a long tail, and capable of biting through a stick half an inch in diameter. It lives either upon small marine or land animals.

The family *Testudinidæ* (Land Tortoises) have their armour thicker and stronger, in proportion to their size, than the aquatic species. The legs are short, and the feet clubby, shaped somewhat like those of the elephant, and adapted for walking on firm ground only, as the



Tortoise.

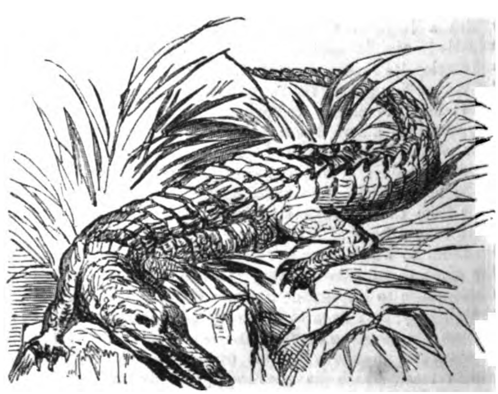
surface they present is very small. The animals are inoffensive, living chiefly upon roots and vegetables, and the insects which infest them. They dig burrows for themselves in which to sleep over the winter. Some individuals of the family have been known to live to an age extending over four or five human generations.

There is a genus differing from the above, and named the *Trionyx*, from having three of the toes on each foot furnished with claws. The carapace and plastron are not completely ossified, and are covered with a soft skin. The animal is highly serviceable in the Nile and other rivers in destroying young crocodiles and alligators.

ORDER SAURIA have generally four short legs; their mouth is always armed with teeth; their toes are furnished with nails, or the feet are palmated or webbed, according to their terrestrial or aquatic habits; the tail at the base is almost as thick as the body itself.

This order comprehends five families—Crocodiles, Lizards, Iguanas, Chameleons, and Scincoidiens.

Family *Crocodilidæ* (Crocodiles) are inhabitants of the rivers and fresh water of the countries bordering on the equator. They are huge and formidable animals, frequently attaining a length of twenty and thirty feet. The head is large, and each of the jaws, which are of an enormous length, is furnished with a single row of teeth. The back and tail are covered with strong plates or shields, so placed as to permit of free motion in all the parts of the body and limbs. The back is



Crocodile.

impenetrable to a musket-bullet. The legs being short and the feet palmated, the motion of the animal on land is necessarily slow; but in the water it moves with great rapidity, the tail acting as a large and powerful oar. This instrument, in which the scales assume the form of a serrated ridge, is a formidable weapon

of defence or attack. Like the vulture, the crocodile usually feeds upon the decayed carcasses that may come in its way; and it is thus of considerable service in those hot countries which it inhabits. But when it kills for itself, it frequently secretes the body of its prey in some hole at the edge of the water, where it is suffered to putrefy, after which it is swallowed without being masticated. The eggs, which are about the size of those of a goose, are deposited in the sand, and hatched by the heat of the sun. The females guard their young for the first three or four months of their existence, during which time they are in considerable danger of being devoured by the males, and other animals. There is only one genus of this family, *Crocodilus*, containing three species—1. The true *Crocodile*, which abounds in the Nile; 2. The *Alligator*, found in the large rivers and swamps of North and South America; and 3. The *Gavial*, which inhabits India and the islands of the Eastern Archipelago. The Malays consider the hunting of these animals excellent sport. Large parties, armed with pikes, pursue them in the marshes, and kill vast numbers of them.

Family *Lacertidæ* (Lizards) have the body elongated, and in general appearance resemble the Crocodile, though in point of size they bear no comparison to it. They are characterised by long slender tongues. Cuvier divides them into two genera—the Crocodile Lizards, and the True Lizards.

The Crocodile Lizards (*Hydrosauria*) derive their familiar name from their large size—some of them measuring upwards of six feet in length—and from having a crest of spines, similar to that of the crocodiles, upon the tail. In many species, also, the plate-coverings resemble those with which that animal is defended. They are sometimes called Monitors, because they warn each other of the approach of an enemy by a shrill whistling sound. They are mostly inhabitants of South America, frequenting the rank herbage of the savannas and the sides of rivers, where they feed almost exclusively on vegetable substances. Their flesh is considered a great delicacy.

The True Lizards (*Lacertæ*) are distinguished from the Hydrosaures by being covered with scales instead

Lizard.

of osseous plates or shields; as also by being strictly terrestrial in their habits, as their rounded tail indicates. This genus, by no means numerous, contains some of the most beautiful species of the saurians. Most of the European, and nearly all the British Lizards, belong to it. They vary in size from five to thirty inches. Their food consists of insects, frogs, and small mammals. They shelter themselves in old walls and dry places, and, except in tropical countries, pass the winter in a state of torpidity.

Family *Iguanidæ* (Iguana, or Guana Lizards) are so called from the name given to many of them by the natives of tropical America, where the most typical examples are found. They are chiefly distinguished from the true lizards by a short and thick tongue, with the extremity very slightly cleft. They live chiefly among the branches of trees, feeding upon leaves and fruit, together with insects and eggs.

This family has been divided into five genera—Iguana Proper, Gecko, Stellio, Polychrus, and Anolis.

Iguanas, properly so called, are, like the true lizards, covered with small imbricated scales; but are distinguished from these by a dorsal crest, and by the slender and compressed character of their tail. They also differ from them by having a large thin fold of skin, or dewlap, under the chin, and porous tubercles in the thighs. Each jaw is furnished with a range of triangular teeth, with the edges finely sharpened, and a double row also on the palate. They feed on vegetable substances, and live chiefly upon trees, though they frequently enter the water. Many of the species attain a length of four and five feet; and both their flesh and eggs are esteemed delicate food.

The *Geckoes*, or Nocturnal Lizards (*Platydactylus*), have not the attenuated form we generally find in reptiles of this order, but have a flattened body and a broad head, which, aided by their sombre colour, gives them a disagreeable appearance. Though the Geckoes are timid and harmless, they are always regarded by the vulgar as having a venomous character. They frequent buildings. Most of them present a curious organisation of the foot, by which the sole is converted into a sucker, enabling the animal to creep up vertical walls and along ceilings, like the flies upon which it feeds. They are common in the warm climates of the Old and New World.

Stellios have the depressed head and body of the Geckoes, and much of the same forbidding appearance; they are chiefly distinguished from them by their tails, which are encircled with rings of large scales. Their neck is narrow, and the head generally much enlarged behind by the muscles of the jaws.

The Marblets, *Polychrus* (πολύς, many, and χρόα, colour), are furnished with a large lung, which fills nearly the whole body, and subdivided into numerous cavities, gives them the power of changing their colour like the chameleon. Their ribs surround the abdomen, and form complete circles; and the tail, which is round, is more or less prehensile. They have no crest.

Anolis is the vernacular name in the Antilles of the lizard, to which the generic term Anolis is applied. They are remarkable for the faculty of inflating an appendage under the throat. They are light and agile in their movements; and in the beauty and brilliancy of their colour exceed all others of the saurian order. One species, the Basilisk, is distinguished by a mitre-shaped crest on the top of its head.

Family *Chameleonidæ* (Chameleons) are animals of

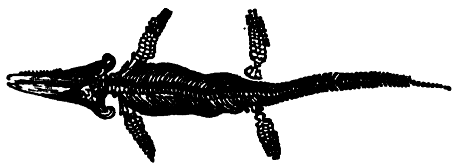
Chameleon.

small size, with a prehensile tail. They are readily distinguished from the other lizards by having scansorial or climbing feet, similar in their general structure to

those of parrots. They are natives of the warm parts of the Old World, and live in trees, which they seldom leave. Their prey, consisting of flies and other insects, is taken by darting out the tongue, which is terminated by an adhesive disk. They are capable of directing their eyes in two different ways at once—a faculty useful in giving information of the proximity of food in any direction. They are also remarkable for the power they possess of changing their colour, which is supposed to arise from the layers of the skin containing two kinds of pigment, situated at different depths.

Family *Scincoidæ* (Skinks, or Serpent-like Lizards) are so called from their general resemblance to snakes. Their feet are very short, their body much elongated, and they are for the most part covered with serpent-like scales.

Geology has made us aware that there was a period in the history of the globe, during which animals of this order, exhibiting some highly peculiar features, were the chiefs of creation, no mammalian animals then existing. The *Ichthyosaurus* was a marine animal, sometimes as



Ichthyosaurus.

much as twenty feet in length, possessing the vertebræ of a fish, with paddle-feet, like those of a turtle, and a crocodile-like head, armed with sharp and formidable teeth. Its fossil remains abound in the lias and oolitic formations. The *Plesiosaur* was a smaller animal, with a neck of extraordinary length, and a small head. It probably swam about on the surface of the water, arching its long neck in all directions on the outlook for fish, at which it would be able to dart its head, even to the depth of several feet. There were also land Saurians, of colossal size, the Megalosaurus, Geosaurus, and Iguanodon,

Pterodactyle.

the last being so named from its teeth resembling those of the Iguana Lizard, arguing herbivorous habits. But the most singular fossil saurian is the *Pterodactyle*. By

Flying Lizard.

an extraordinary development of the last digit, it was furnished with a pair of large wings, like those of the bat, and thus is supposed to have been enabled to pursue insects in the air. The only animal of the existing time approaching to the character of the Pterodactyle is the *Draco Volans*, or Flying Lizard, a small creature, possessing a membrane at its sides, by which it can float, as upon a parachute, from one tree to another.

Order Ophidia have the remarkable distinction of being destitute of limbs, yet are in their general characters so like saurians, that some naturalists decline to consider them as a separate order. In the possession of teeth, and in the scaly covering of their bodies, as well as in their general internal organisation, they closely correspond with the lizard tribes; and a further connection is shewn in the fact, that while some lizards have only two feet, some serpents shew the rudiments of the same number of limbs, though of no observable use. The serpents appear designed for a furtive life in grass and shrubbery, where they prey upon small animals. Their elongated bodies move in three ways—by alternate extensions and contractions, after the manner of worms, and by a series of arches, the straightening of which causes the head to keep continually advancing. 'They also coil themselves into a spiral by contracting the muscles on one side of the body, and by suddenly throwing into action those on the opposite side, the body being propelled as by the release of a powerful spring, with an impulse which raises it several feet from the ground, and projects it to a considerable distance.' They remain torpid during winter, and each season cast their skin. The tongue is forked. All are furnished with teeth, of which the greater number of species have three rows. A smaller number have only two rows; but as if to make up for that comparative weakness, these possess two fangs, containing poison—a peculiarity, it may be remarked, always inferring feebleness, or the want of other means of defence, in the animals exhibiting it. The serpent has from two to three hundred vertebræ; the head is small, but for its size has a large swallow, so as to admit of the prey being eaten entire. Like lizards and tortoises, the serpents are oviparous; but in some, the eggs are retained so long as to be in a manner hatched within the body of the parent, and thus are born alive.

The order comprehends five families.

Family *Anguinidæ* (Slow-worms) are generally of small size and harmless. In their structure they make an approach to the lizards, the bones of the pelvis and shoulder existing in a rudimentary state under the skin. The common Slow-worm, or Blind-worm, of this country has received its second name from the supposed absence of eyes; this is an absurd error, however, as the eyes, though small, are very brilliant. It is a perfectly harmless animal, feeding on insects, slugs, &c. It is said to swallow frogs, birds, and mice; but this is impossible, as the bones of its jaw do not separate in the middle, and its swallow is consequently small and not dilatable. When alarmed, it throws the whole of its muscles into contraction in a peculiar manner, and is then very brittle, so that it frequently loses its tail by various accidents; in the course of a year, however, this member is replaced. There is a larger species of this family existing in America, which attains the length of two feet, and from its extreme brittleness is called the Glass-serpent.

The *Hydrophidæ* (Water-serpents) are comparatively few, and are limited in their geographical range. They are mostly found in the seas and rivers of the East Indies, and in some localities they are by no means uncommon. They are chiefly known by the very decided vertical compression of the tail and hinder part of the body, which may thus be compared to the tails of fishes; hence they swim with considerable facility, occasionally coming to the surface to respire. They possess poison-fangs, and are more dangerous than crocodiles or sharks to persons entering the water where they abound.

The *Amphisbænidæ* (Double-walkers) are a still

smaller group, intermediate in some respects between the slow-worms and the true serpents. They derive their name from the power of moving backwards or forwards with equal facility. The two extremities of the body are so much alike, that they would not be distinguished by a superficial observer, the eyes being so very small as sometimes to appear wanting; the whole body is of nearly equal diameter. This group is restricted to the warmest parts of South America. Notwithstanding the common idea of its venomous properties, it is quite harmless, and subsists on ants and other small insects. It has not the power of separating the bones of the jaws, which distinguishes the true serpents.

Family *Crotalidæ* includes the great bulk of the venomous species. Their type is the Rattlesnake, so called from the sound produced by a series of horny rings at the extremity of the tail when the animal is in motion. The poison-fangs are each pierced by a small canal, which gives issue to a poisonous fluid. When not in use, these lie incased in the upper gum; but when the animal is irritated, they are unfolded, and struck into the victim, the poison being at the same time ejected with great force by the action of the muscles that shut the lower jaw. The matter is poisonous only when introduced into the blood. The bite of the rattlesnake produces almost instantaneous death; but they never attack man unless when trodden on or provoked. Their food consists of birds and small animals; and such is the terror with which they inspire these creatures, that it often renders them incapable of saving themselves by flight. This may have given rise to the supposition that rattlesnakes had the power of fascination. Some species are from five to six feet in length, and about the thickness of a man's arm. Besides their other peculiarities, this genus is also remarkable for a deep hole behind each nostril, the use of which has not been ascertained.

The Vipers (*Vipera*, a contraction of *vivipar—virus*, alive, and *paro*, I bring forth) are produced from eggs; but in the act of deposition, the covering is broken, and the young come forth alive. They are distinguished from the former genus by a broader head, and by the absence of the rattle, as well as the cavities behind their nostrils. Vipers are most abundant in hot countries, where they attain the largest size. The Common Adder and the Black Adder are the only two species of venomous serpents indigenous to Britain.

Puff Adder.

Family *Coluberidæ* (True Snakes).—This group, which is non-venomous, and very extensive, includes all those serpents in which the subcaudal plates are arranged in pairs, thus comprising the largest serpents in existence. Most of the family have the greater number of the characteristic properties of the order highly developed. This family, *Coluberidæ*, consists of Boas, Pythons, and Colubers.

The *Boa Constrictors*, which are peculiar to the tropical regions of America, are characterised by having the under part of the body and tail covered with transverse shields. Many of the species have been known to exceed forty feet in length, and they can swallow large animals, such as sheep and even oxen. This they effect by coiling themselves round the body of the victim, and crushing it till every bone is broken. They then moisten it with saliva, and proceed to swallow it. The *Pythons* are inhabitants of Asia, and differ from the Boas principally in having the plates under the tail double. Though many of them are as large as the Boas, yet they feed on birds, rats, and other small animals. The serpents exhibited in this country under the name of Boa Constrictors are mostly Pythons. The *Colubers*, properly so called, are inhabitants of Europe. They sometimes attain a length of six or seven feet. In appearance they resemble the Pythons, and, like them, feed on small animals—such as insects, mice, and frogs. They prefer marshy situations.

There is also an important group of coluberiform serpents which are venomous, inhabiting India and Africa. They are externally distinguished by little more than the comparative thickness of the muzzle.

Cobra da Capello.

The most formidable of the group is the *Cobra da Capello* of India, the bite of which is fatal within an hour.

ORDER BATRACHIA (from Βάτραχος, a frog) includes frogs, toads, and such reptiles as have no scales, but a naked and moist skin. They are remarkable for a curious peculiarity attending their reproduction. On issuing from the egg, they are in an immature state, possessed of gills, and thus fitted to live in the water. The order comprehends three families, respectively represented by the Frog, Toad, and Newt.

Family *Ranidæ*, or Frogs (*rana*, a frog), are so well known that a description of them seems unnecessary. Their power of leaping is remarkable, and they are the best swimmers of all four-footed animals. They are of a yellowish brown colour, with black spots. Their mode of breathing is one of the most curious characteristics in their organisation. Their inspiration is effected by the muscles of the throat, which, by dilating, draw in air through the nostrils. The contraction of these muscles, while the nostrils are closed by the pressing of the tongue against their interior orifices, and the mouth at the same time being shut, compels the air to enter the lungs. The animal would thus be choked if the mouth were kept open. Their expiration, on the other hand, is produced by the contraction of the muscles of the abdomen. In cold regions, frogs pass the winter in the ground, or in mud under water, without eating or

breathing. The spawn, consisting of a vast number of eggs, each of which is surrounded by a covering of transparent glutinous matter, is deposited at the bottom of some stagnant pool early in spring. Owing to some partial decomposition, and the consequent disengagement of a gas, the entire mass becomes lighter than the surrounding water, and rises to the surface. The young then burst from their prison, and feed on vegetable matter. In the early stage of their existence, they are called tadpoles, and are of a black colour. They breathe by gills, and are characterised by a round head and long tail. In this state, they may be regarded as fish in all essential respects. They increase for a time rapidly in size, without undergoing much change in form, till they attain a length of about an inch. The hind feet are then developed; next, the anterior extremities assume their ultimate form, the tail is gradually absorbed, the hinder part of the body becomes rounded, and the beak falls off, discovering the true jaws. The eyes, which in the tadpole were only discerned through a transparent spot in the skin, become visible with their three lids; the gills are obliterated. As soon as they have effected their metamorphoses, they breathe by lungs, and become carnivorous, feeding upon insects, slugs, and similar animals. The Common Frog (*R. Temporaria*) is the only species indigenous to Britain.

The *Surinam Frog* is remarkable for being much smaller in the mature than in the immature state, the tadpole being fully eight inches long, while the frog is diminished, chiefly by the loss of its tail, to three.

The Tree-frogs (*Hylæ*) differ from the common frogs chiefly in having their feet provided with suckers—a conformation which enables them to adhere to the surfaces of bodies, and even climb trees. This they do in pursuit of insects. These also lay their eggs in the water, and hibernate during winter. They are natives of America, and many parts of Europe; but are never found in Britain.

Family *Bufoidæ* (Toads) resemble the frogs in figure, but are of a dull cadaverous hue, and covered with warts. Their movements are slow. They are characterised by a swelling above each eye, from which a fetid milky excretion is expressed; but this is said to be destitute of any venomous quality. They are useful in gardens, as they feed on worms, slugs, and wasps; yet they are hated and persecuted by the ignorant. They seldom frequent the water, but for the purpose of depositing their eggs. Their hibernation is passed on land, either in some sheltered space, or in burrows which they excavate for themselves beneath the surface of the ground. Two species are found in Britain, the *Common Toad* and the *Natterjack*. The former progresses more by leaping than crawling; and the latter does not leap, but creeps, which it does with considerable celerity. The natterjack is found in the heaths of the south of England. Other species are the *Bombinator*, the *Rhinella*, the *Antilophus*, the *Breviceps*, and the *Pipa*.

The family of Salamanders, the largest of which does not exceed two feet in length, have the body and tail elongated. They bear a strong resemblance to the lizards in their general form, but are easily distinguished from them by their smooth soft skin. They may be subdivided into three genera—the True Salamanders, the Tritons, and the Amphibious Newts.

The *True Salamanders* remain in the water during their tadpole state. In their adult condition, they live principally on the land, and frequent their original element only for the purpose of depositing their young, which are produced alive. There are few of these reptiles in Europe; in America, many have of late years been discovered. The surface of their bodies, like that of the toad, is somewhat warty, and they have a gland containing an acrid secretion said to be poisonous. Their tail is cylindrical, or rounded. Eggs are hatched within the body, and young are produced alive. These animals prefer damp and humid places, particularly at the edges of walls, hiding among rank grass, where their food, which consists of slugs and worms, is readily procured.

Newt.

The *Tritons*, or *Aquatic Salamanders*, commonly called *Newts*, pass the greater part of their life in the water. Their tail, which is their chief organ of locomotion, is vertically compressed, or oar-shaped. They possess the extraordinary power of reproducing limbs that have been cut off. There are three species indigenous to Britain.

The *Amphibious Newts* (*Amphineusta*) which are similar in form to the two preceding genera, breathe both by lungs and gills, respiring by the former on land, and by the latter in water; and are the only true amphibians among vertebrated animals. This genus, consisting of the Proteus, the Syrens, and some others, are chiefly inhabitants of the American continent.

CLASS BIRDS.

The third class of vertebrated animals is the BIRDS, in which we for the first time find a complete double system of circulation, attended with its proper consequence of warm blood, while yet they maintain the oviparous mode of reproduction which we have seen in Reptiles, only with the additional peculiarity of a hatching and nurturing of the young by the parent. The most remarkable external features of the class are—the having the body covered with feathers instead of hair or wool, and, as a rule, the fore-pair of limbs adapted to serve as wings, in enabling the animal to maintain flight in the air. In their internal structure, birds are distinguished by having the lungs, which are larger than in the mammalia, fixed to the ribs, and pierced in such a way as to permit the air not only to pass into the chest, but also into various other cells, that can be inflated or emptied at pleasure. This organisation, by increasing their buoyancy, adapts them to range over the aërial regions with an ease and celerity to which there is no parallel in nature. Their powers of vision are more highly developed than those of any other class of vertebrated animals, the eye being generally so constructed that they can see objects far and near with almost equal clearness.

The posterior extremities of birds serve as the sole support of the body on the ground, and are usually placed rather far back. Most commonly, the feet exhibit four toes, of which one is directed behind and three in front; besides which there is, in the fowl tribe, a *spur* behind, analogous to the thumb on the human hand. In the ordinary single posterior toe, the number of joints is only two; in the external, it is five. The toes terminate in claws, and these are of great strength and sharpness, where they are to be used in clutching and tearing prey.

Birds have no teeth, properly so called, and cannot therefore masticate their food, which is either torn by the beak or swallowed whole—its reduction to a soft and pulpy state being entirely performed in the stomach. The plan of the digestive system most usual in this class is that which is exemplified in the common fowl. The stomach consists of three cavities: the first being formed by an expansion of the gullet, which produces a bag or chamber known as the *crop*. In this receptacle the food is stored up, and transferred by degrees to the second or membranous stomach, where it is softened by the action of the gastric-juice. It is then conducted to the *gizzard*, or third cavity, in which the process of digestion is completed. This last stomach presents modifications varying with the nature of the food upon which the bird subsists. If it feeds on grain, the sides of this stomach are of considerable thickness, and are moved by powerful muscles, which act as a mill in grinding down the food; but in those species which subsist on animal substances, or soft herbage, the muscles are reduced to extreme delicacy. In many cases the process of digestion is promoted by the swallowing of small pebbles, which, being brought into contact with the food in the gizzard by the muscular action of the stomach, produce an effect similar to that of teeth, and in some measure serve the purpose of these agents.

The change of the plumage, termed *moulting*, generally takes place annually; while with some species a partial casting of the feathers occurs also at the breeding-season. Many birds migrate from one latitude to another, chiefly for the sake of obtaining a better supply of food. The summer immigrants that visit our island—as the swallow, the rail, and the cuckoo—are from tropical regions; while all winter visitants—as the swan and the wild-goose—come from the north. The northerly position is the one adopted by the latter for their summer residence, and the bringing forth of their young.

Not only do birds resemble insects in their general structure and mode of life, but also in the peculiar development of the instinctive powers. Under the direction of these, the place for their nests appears to be selected, their materials collected, the nests themselves built, and the young reared in them, the migrations are performed, and many curious stratagems are employed to obtain food. It is sufficient thus to indicate these features in general terms, since it is well known that each species has some peculiar habits, while in all the individuals of each, they are as precisely alike as their circumstances will admit. Nevertheless, there is observed in birds a degree and adaptation to varying conditions which insects do not possess, and an amount of *intelligence* superior to what is found in that class. And in the domesticability of many tribes of birds, we see an obvious approach towards that higher form of attachment to man which is exhibited by many species among mammalia.

Birds are of great utility to man, not only as an article of food, but also by keeping in check noxious animals; as insects and snakes, and in consuming carrion and other refuse.

Natatores.

ORDER NATATORES, or *Swimmers*.—A considerable number of the birds are adapted to an aquatic life, and spend great part of their time upon the surface of the sea, or on rivers and lakes. These are regarded as forming a distinct order, characterised by that webbed form of foot which serves for swimming, and named accordingly *Swimmers*, though in reality the order includes birds of great variety of character, both in form and in disposition and habits. The legs are short, and placed behind the point of equilibrium. The body is closely covered with feathers, and coated with a thick down next the skin. It is in this order that we find the nearest approach to reptiles which is to be found amongst the birds.

The *Alcidæ* (Auk tribe) exhibit the most remarkable adaptation of the structure of the bird to an aquatic life, with which the entire order presents us. This is best seen in the *Penguins*, whose wings are very small, and covered with mere vestiges of feathers, resembling scales; so that they serve as admirable fins or paddles, but are totally useless for flight. The feet are placed very far back, so that when upon land the bird stands nearly erect. Having no power of flight, and not being able to run, the penguin may be overtaken with ease upon land; but once in the water, it distances its pursuers, swimming with the ease and rapidity of a fish, and springing several feet over any obstacle that may impede its course. Besides other characters which are considered as indicating an approach towards the reptiles in this tribe, the penguin is especially remarkable for having the kind of ball-and-socket union of its vertebræ which is peculiar to that class. They are exclusively inhabitants of the southern seas; but there are birds of the northern ocean which approach them in their peculiar characters. Such are the *Puffins* and *Auks*, the former of which have short wings, capable of sustaining them for a little while; of the latter, one species has wings well adapted for flight, whilst in the others the wings are adapted to aquatic progression almost as exclusively as in the penguin. The Puffin, which comes to Britain both from the north and south, and is often found breeding in old rabbit-holes near the sea, has a short deep narrow bill, and horny appendages over its eyelids. Watching on

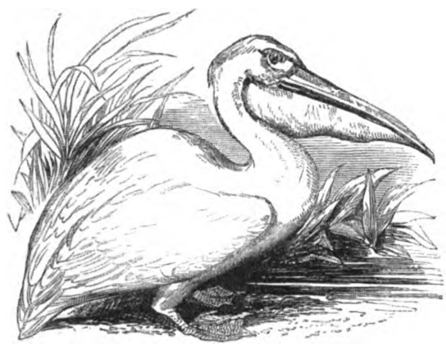
Puffin.

cliffs over the sea, it no sooner sees a proper prey, than it plunges like a dart into the water, and often captures three or four sprats at once.

In the family *Colymbidæ* (Divers), as in the penguins, the wings are remarkably short, and the feet placed so far behind the point of equilibrium of the body, that they are ill adapted for walking. Of the genus *Colymbus*, the *Northern Diver* is a familiar example. It is generally an inhabitant of the most northern parts of the Old and New World; but on the approach of winter, it journeys southward, and is then occasionally found in Scotland. It is said to be able to swim below the surface of the water for a couple of hundred yards, in pursuit of its prey, which consists of small fish. The *Guillemots* bear more resemblance perhaps to the auk family, but resemble the divers in using their wings to propel themselves under water. The *Grebes* (*Podiceps*) are more inland in their habits, living chiefly on the borders of lakes. The toes are separate, but each has a fin-like membrane along the side, presenting a considerable surface to the water.

Family *Pelicanidæ* (Pelicans) consists of three genera, represented by the Pelican, Cormorant, and Solan Goose.

The *European Pelican*, which may be taken as a representative of the Pelican genus, is as large as a swan,



Pelican.

and altogether white. It has a long, slightly curved bill, and is remarkable for possessing a large neck-pouch, in which it stores provisions and water. The bird makes its nest in marshes, but roosts on trees.

Genus *Phalacrocorax* (Cormorants).—The *Black Cormorant* is about the size of a goose, and of a bronze black colour. It is very common on the British coasts, and in former times it was trained in Europe, and still is by the Chinese, for fishing, as hawks are for fowling. The cormorant is proverbial for its voracity. It carries on its ravages by night and by day, diving to catch its prey, which it can pursue for nearly one hundred yards below the water, before it is obliged to come up for air.

Genus *Sula* (the Gannet or Solan Goose).—These birds take their prey by hovering in the air at some little distance above the surface, and then dropping down upon any fish that they may see rising within their reach. The air-cells are very largely developed, especially under the skin of the breast, which is almost completely separated by them from the muscles beneath; and it is probable that they may serve as an elastic cushion, to break the force with which the body of the bird would otherwise impinge on the water. These birds haunt the cliffs of solitary islands, for the purpose of bringing forth their young. The Bass Rock in the Firth of Forth, and Ailsa in the Firth of Clyde, are noted habitations of the *Solan*. It is eatable, but forms rather a coarse dish for most palates.

Family *Anatidæ* (Ducks) is divided into three genera, represented by the Swan, the Goose, and the Duck.—They are all remarkable for a broad bill, horny at the extremity, while the rest is invested in a membrane, and terminates at the edges in laminæ or little teeth, forming a kind of strainer for gathering food in a watery element. The birds of this family are highly serviceable as food.

Genus *Cygnus* (Lat., a Swan).—There are several wild species of this genus, of which the most remarkable is the *Hooper* or *Whistling Swan*, a native of the arctic regions, but which migrates southward in flocks, headed by a leader, and ranged in the form of the letter V, when their loud notes are occasionally to be heard, softened by distance. The tame Swan (*C. olor*), called the *Mute Swan*, to distinguish it from the preceding, is a beautiful ornament to our rivers and lakes. It is one of the most elegant birds, lives almost entirely upon the waters, and feeds upon aquatic plants, frogs, and insects. Swans are remarkable for their longevity, some having been known to live a hundred years.

Genus *Anser* (Lat., a Goose) presents several wild and migratory species both in the Old and New Worlds. They all live upon vegetable substances, and are consequently useful as food. The *Canada Goose* going northward every summer, is of great service to the Hudson's Bay residents, who kill and preserve great quantities for their winter provision. Our own tame species is supposed to be derived from the *Gray Lag Goose*, once very abundant in the fenny districts of Lincoln and the neighbouring counties, and permanently resident, but, like other species, now only seen in small flocks as a winter visitant.

Eider Duck.

Genus *Anas* (Lat., a Duck) includes many species, as the Velvet Duck, the Eider Duck, Shoveller, and Sheldrake; all of them wild animals, frequenting pools and other waters remote from human haunts. The *Mallard* is the parent race of all the common ducks. It is permanent in many parts of Scotland in lakes and marshes, but receives a vast accession to its numbers on the approach of winter from northern countries. The habits of the *Common Duck* are familiar: in its researches for food amongst mud and turbid waters, it is understood to be much assisted by the sensitive skin of its bill, which enables it to feel, or, as it were, grope for objects which it may devour.

Family *Laridæ* (Gulls).—This tribe performs the same office on the sea that vultures do on land, feeding upon carcasses of every description that float on its surface, or are cast upon its shores. They are found in all latitudes, but are larger and more numerous in the northern regions. They are arranged into five genera—Gulls, Terns, Skuas, Petrels, and Albatrosses.

Genus *Larus* (Gulls Proper).—The *Common Gull* (*L. vulgaris*), the type of the genus, is about one foot and a half in length, and three feet in the expanse of its wings; above, it is of a bluish-gray, and white beneath. It makes its nest of sea-weed, on the ledges of rocks on the coast. On the approach of stormy weather, it has a propensity to leave the shore, and to sail round and round in circles at a great elevation.

Genus *Sterna* (Terns) are sometimes called *Sea-swallows*, from the resemblance they bear to the land-swallow in their long pointed wings and forked tail. They are also similar to that bird in their port and flight, but differ very much from it in their habits. Their food consists of mollusks and small fish. The tern is often seen chasing a small gull, and, as it were, persecuting it, in order to force it to disgorge the fish it may have taken. As soon as the fish has been dropped, the tern descends like an arrow, and generally succeeds in catching the meal before it reaches the surface of the water. The *Common Tern*, which is about fourteen inches in length, is a periodical visitant in Britain, arriving in April and leaving in September. In very stormy weather, it may be seen following the river-courses in pursuit of its prey.

Genus *Lestris* (Skuas) are nearly allied to the Terns, but are more powerful birds. Their peculiar habitation in this country is the Shetland Islands, where they nestle and breed in communities on wild and unfrequented heaths; but as soon as the breeding has ended, they go each its own way to the adjacent seas, and lead a solitary life, feeding on fish-offal and animal matter. Like the terns, they pursue gulls till they oblige them to disgorge what they have swallowed. The entire length of the *Common Skua* is about two feet; the wing measures sixteen inches, and its general colour is a reddish-brown.

Genus *Procellaria* (Petrels).—The name *Petrel* is a diminutive of Peter, and has been applied to those birds from their habit of walking on the waves. This they effect by striking their feet rapidly against the water, and at the same time supporting themselves with their wings. One species, the *Giant Petrel*, is as large as a goose; it is found only in the South Seas. The most common one, called by mariners *Mother Carey's Chicken*, is found in most seas. When it seeks shelter upon vessels, it is generally supposed as indicative of storms and shipwrecks. During the greater part of the day, it conceals itself in holes and crevices of rocky shores; in the evening, it comes forth, and flies close over the surface of the sea, in search of floating insects and dead animal matter. This species is of a brownish-black, and it differs little from the common swallow either in size or appearance.

Genus *Diomedea* (Albatrosses).—The *Common Albatross* (*D. exulans*) is the most bulky of all aquatic birds, measuring twelve feet and upwards between the extremities of the wings, and has a wide range upon the ocean, but abounds chiefly within the tropics. It has a large, strong, trenchant bill, marked with sutures or joinings, and terminating in a stout hook. It is very voracious, and is said to destroy numbers of flying-fish, when they are forced to seek refuge in the air.

Grallatores.

The Order of Grallatores (*Waders* or *Stilt-birds*) derive the name from their habits and conformation. Their long legs raise up their bodies, as it were upon stilts, and thus elevated, they frequent the banks of rivers, lakes, marshes, and the shores of estuaries; and whilst resting with their feet upon the land, derive their nourishment chiefly from the water—some feeding exclusively upon small fishes, aquatic mollusca, worms, small reptiles, and water-insects—whilst others are more terrestrial in their habits and mode of feeding. Such as are more especially aquatic have a short web to their toes. Their wings are long, affording them that power of changing their habitation with the seasons, which most of them enjoy. During flight, they stretch out their long legs behind, to counterbalance their long necks; and the tail is always extremely short, its function as a rudder being transferred to the legs. They mostly construct their nests upon the ground; and the young are enabled to run about as soon as hatched, except in those species which live in pairs.

Family *Gruidæ* (Cranes).—Of this family we shall notice only one species, the *European Crane* (*Grus*

Crane.

cinerea). In Britain its appearance is now exceedingly rare, though in former times it was well known in many parts of England. It is described as a beautiful sight to witness thousands of them passing over the Mediterranean, northwards and southwards, as the case may be, in marshalled order, in groups of from twenty to sixty, and each group headed by one of the larger birds. It is with reference to the regularity of the migrations of these birds, that Jeremiah, viii. 7, says: 'Yea, the stork in the heaven knoweth her appointed times.' The crane roosts on the ground in open situations void of trees, and its food consists almost exclusively of vegetables. Its length is nearly five feet, and its weight about ten pounds.

Family *Ardeidæ* (Herons).—The *Common Heron* (*Ardea cinerea*) is of very general distribution, and is a well-known bird in Britain. It passes the winter in the southern parts of Europe and in the north of Africa, migrating thither in autumn, and returning northward in spring. The extreme length of the Heron is about three and a half feet; its general colour is an ashy gray with a bluish tinge; and its head is ornamented with a crest. It builds on lofty trees, especially on oaks, in the neighbourhood of streams and marshes. The heron is very expert in catching fish, on which it principally feeds, though it does not despise mice and reptiles.

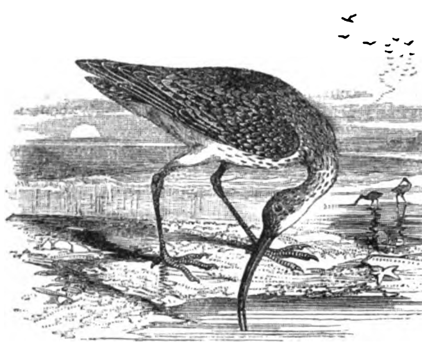
The *Bittern* or *Mire Drum* (*Botaurus stellaris*), a species of heron, was once well known in Britain, but is becoming rare as waste lands are reclaimed. Its general resorts are extensive swamps covered with tall flags and rushes. The bittern is the emblem of desolation, and as such is spoken of by the prophet in his denunciation against Babylon: 'I will also make it a possession for the bittern, and pools of water: and I will sweep it with the besom of destruction, saith the Lord of hosts.' The booming of the bittern is peculiarly dismal. It resembles the interrupted bellowing of a bull, but is more hollow, and is heard at the distance of a mile. From this circumstance, and the lonely marshes it inhabited, it was the unconscious hero of many a ghost-story in the superstitious ages that are past.

The *Stork* (*Ciconia alba*) stands about four feet high. It migrates in summer from Africa into a wide range of more temperate latitudes, and, in many countries widely apart from each other, is held, as it were, sacred, on account of its destruction of vermin. This has rendered it very familiar, and in Holland they prepare false chimneys on the tops of their houses, that the stork may build in them, each regularly returning to its own nest every year. Owing probably to the improved drainage of the country, the stork is now a rare visitor of Britain.

The family *Scolopacidæ*, composed of Snipes and Woodcocks, has the Wood-cock (*σκολόπαξ*) for its type. These birds are remarkable for their long and slender bills, the use of which is restricted to searching in the mud for worms and insects. To this family belongs the *Ibis*, an African species, once held in great veneration in Egypt, and embalmed by the ancient people of that country, in consequence, it is supposed, of its usefulness in devouring serpents.

The *Wood-cock* is a well-known species in Britain, where it arrives in flocks from the northern countries. It is about the size of a pigeon, and has finely mottled plumage. It feeds on worms and insects, which it searches for with its long bill in moist situations, under the cover of young trees, and near hedges by the sides of rivulets. As an article of food, it is much esteemed for its exquisite flavour. The *Common* or *Whole Snipe* is one of the most common winter visitants of the British Isles. It chooses swampy parts of meadows; and small worms, insects, and vegetable substances seem to constitute its food. Its entire length is about twelve inches, and weight about four ounces. The *Half* or *Jack Snipe* is a minute species, its length being only eight inches. It resembles the other in its habits, only it is more solitary. The *Curlew* also belongs to this family. It is a well-known bird, haunting sandy shores during the whole winter for

minute crustacea and worms, and breeding in summer on heaths and bogs. The name is derived from the bird's peculiar cry.



Curlew.

Family *Rallidæ* (Rails) consists of five genera—Gallinula, Fulica, Rallus, Jacana, and Phœnicopterus.—The *Water-hen* is a species very common throughout Europe. In summer, it is found in almost every pond, lake, and quiet water-course. Its colour is a deep olive-brown above, and slaty-gray below, with a frontal shield of bright red. It is rather more than a foot in length, and weighs about fifteen ounces.

The *Coot* (*Fulica atra*), a well-known bird, found wherever there is a pond, is migratory, and arrives here in large flocks from more northern latitudes, though many of them are constantly resident. Its size is equal to that of a common fowl.

The *Rails* (*Rallus*).—The *Landrail* or *Corncrake* (*R. pratensis*) is a regular summer visitant in the British Isles. It conceals itself so well among the grass and young corn, that were it not for its cry, few persons would be aware of its presence amongst us. It is larger than a black-bird, and is of a reddish-brown colour.

Landrail.

The *Jacanas* and *Flamingoes* are classed with the Rail family. They inhabit the marshes of hot countries. The common species of the flamingo, *Phœnicopterus* (wings of flame), is from three to four feet in height. It is purple-red on the back, and has rose-coloured wings. The mandibles are abruptly bent downwards, about the middle of their length; and they are roughened at the edges, like those of the ducks, to which the fleshiness of the tongue also shews an alliance. They feed on mollusca, insects, the spawn of fishes, &c., which they seize by means of their long neck, turning the head downwards, to use to advantage the crook in the upper mandible. They construct their nests in marshy situations, placing themselves astride of them during the act of incubation, being incapacitated by the length of their legs from sitting on them in the usual manner.

Flamingo.

The *Charadriadæ*, or *Plover tribe*, are less aquatic than most of the other families. The legs are long, and the back-toe is either quite absent, or so short as not to reach the ground. They live only on sandy and unsheltered shores, or on exposed commons, congregating in flocks, and running with great swiftness. The bill is usually of moderate strength, enabling these birds to penetrate the ground in search of worms, to obtain which they have the habit of patting with their feet, which causes the worms to rise. The species in which the bill is more feeble, frequent meadows and newly ploughed land, where this food can be obtained with greater ease; those which have stronger bills subsist additionally on grain, herbage, &c. Of the plovers, several species exist in Britain, and others are distributed through most other countries. Some chiefly frequent the sea-coast, and others the upland moors. The *Lapwings* are nearly allied to the plovers, and, like them, are migratory, passing the winter in warm latitudes; they are peculiar to the Eastern Hemisphere. They are very noisy birds, screaming at every sound they hear, and defending themselves with courage against birds of prey. They derive their name from the stratagem by which they lure away intruders from their nests: they drop their wings in flight, appearing as if wounded, and thus induce their pursuers to follow them to a considerable distance.

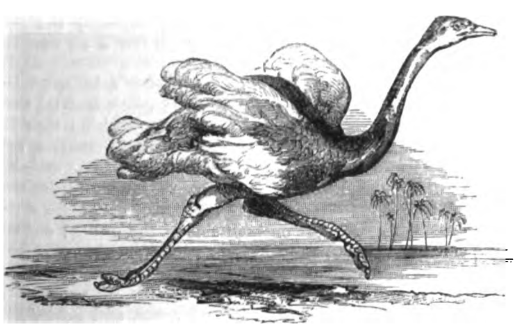
Three other genera of this family are worthy of notice. The *Bustards* connect the Grallatores with the Rasores in the heaviness of their bodies, the small membrane at the base of their toes, and some other characters. They have, however, the long naked legs of this order, and the flavour of their flesh resembles that of the wading-birds. They fly little, scarcely ever using their wings, except, like the ostriches, to assist them in running; but their flight, when they do rise, is easy, and capable of considerable duration. They feed equally on grain, herbage, worms, and insects. The great bustard is the largest of European birds, and is one of the finest kinds of game; it has been nearly extirpated in Great Britain. The *Turnstone* is at once recognised by a short stout bill, rather turned upwards; the name is derived from the habit it possesses of turning up stones on the sea-shore, to feed upon the marine animals concealed beneath. The *Oyster-catcher* has a long, straight, wedge-shaped beak, which is strong enough to enable it to force open the bivalve shells of the mollusks upon which it feeds.

Cursores.

Order Cursores, or *Runners*, exhibit a remarkable exception from the class in general, being without powers of flight, and possessing at the utmost only the

rudiments of wings. Instead of such powers, these birds have remarkably strong limbs, adapted for rapid running over the wide-spread plains which they inhabit. Hence their name as an order. In some respects they approach the mammalian character, their feathers being much like hair, and one of the family having the rudiment of both a diaphragm and a bladder, wanting in birds in general.

The *Ostrich* is a well-known bird in the tropical parts of the Eastern Hemisphere. Its specific name of *Struthio camelus* was conferred in allusion to certain points of analogy between it and the camel; it is an inhabitant of the wide-spread deserts of Africa and Arabia. It is incapable of flight, but is remarkable for its swiftness of foot, being able to outstrip the fleetest horse. The height of the adult male is from seven to eight feet in the upright position. The *Great Bustard* (*Otis tarda*), which may be considered as the European representative of the ostrich, was once common in Britain, where, however, it is now of rare occurrence, being chiefly confined to the county of Norfolk. It runs with extreme rapidity, and, unless closely pursued, seldom takes wing. It frequents extensive plains, and nestles among the corn. Its weight is from



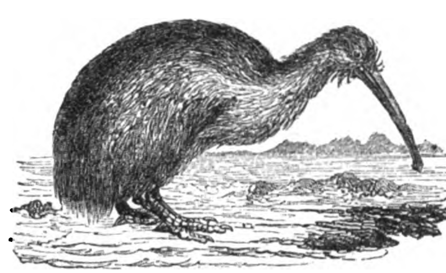
Ostrich.

twenty-five to thirty pounds, and its flesh is much esteemed. The *Little Bustard* (*O. tetrax*) is scarcely half the size of the preceding species, and less widely diffused.

Of the *Rhea*, which is peculiar to South America, there are only two well-defined species. By travellers they are called ostriches. One of the species in its natural attitude stands about five feet high; the other is of smaller size. The plumes of these birds are imported into this country, and are often seen fixed in a handle, so as to form dusting-brushes.

Of the genus *Dromaius*, the *Emu*, or *New Holland Cassowary*, is the type. It nearly equals the ostrich in bulk, but is lower on the legs, and more thickset in body. Though not an aquatic bird, the emu swims well. There is only one example of the genus *Casuarius*, and it is a native of Java, Sumatra, and the Moluccas. Its pinions are very small, and concealed beneath the plumage. The beak, instead of being broad and depressed, as in the ostrich, is compressed laterally, and ridged above. The head, which is naked, is surmounted with a horny crest or helmet. The height of this bird when erect is about five feet, and it is very strong. Its food consists of fruits and tender juicy herbage.

The *Apteryx* is limited to New Zealand. It stands about two feet in height. It has merely the rudiments of wings, buried beneath the general plumage of the body; but, like the ostrich, it runs with great swiftness. When chased, it takes refuge in the clefts of rocks, in hollow trees, or in deep holes, which it excavates in the ground. Its food consists of insects and worms. Night is the season of its activity, and the natives hunt it by torchlight. The skin, prepared with the



Apteryx.

feathers on it, is highly prized by the chiefs as an article of dress.

Rasores.

The Order Rasores (*Scrapers*)—nearly corresponding with the Gallinaceæ, or Poultry tribes—consists of land-birds of bulky bodies, generally vegetable, or rather grain-feeders, gregarious in their habits, and readily domesticable. The name of the order is derived from a noted habit which serves them in seeking for food. They furnish man with a considerable amount of savoury and wholesome food, and their fecundity is very great. The majority of them are at once known by their strong thick legs, long necks, short wings, and large ample tails; and the heads of many, especially of the males, are ornamented with elegant crests. The form of the bill is well seen in the common cock; the upper mandible is vaulted, and at the same time destitute of any notch; the whole is short and strong, having a peculiarly horny appearance. The wings are muscular, but their feathers have rounded ends; and the breast-bone presents a comparatively small surface for the attachment of the muscles, so that the power of flight is not great. Almost all of them have a large crop, and an extremely muscular gizzard.

The Rasores, in general, deposit and hatch their eggs on the ground, in a rudely constructed nest of straw; but some of them, which reside in forests, build in trees. Each male usually associates with many females; he takes no part in the construction of the nest or in rearing the young, and these are generally numerous, and able to run about and provide for themselves the moment they quit the shell. When this is the case, the male is larger and more gaily coloured than the female. But in the few species which associate in pairs, such as the ptarmigan and partridge, the sexes nearly or quite resemble each other, both in size and colour.

The Rasores are usually divided into four families—Pheasants, Curassows, Partridges, and Pigeons.

The *Phasianidæ* (Pheasant or Fowl family) are distinguished by the shortness of the hind-toe, the presence of spurs on the legs, and the beautiful development of the tail. Overlooking the turkey, they are birds of the Old World. They may be considered as forming the type of the order. It is in the hotter parts of India that the most brilliantly coloured birds of this family present themselves in greatest numbers.

The *Pheasant*, which again may be regarded as the type of the family, derives its name from the Phasis, a river of Colchis, in Asia Minor, from which district it was first introduced into Europe. Several very handsome species abound in different parts of Asia. Among these, one of the most remarkable is the *Argus pheasant*, inhabiting Sumatra and the south-east of Asia. The wings are large, and are covered with eye-like spots, which give a very remarkable appearance to the bird. There is a large poultry-bird in New Holland, which has

been sometimes placed among the vultures, but which certainly belongs to this order. This is the *Vultern:* its chief point of resemblance to the vultures is its bald neck; it has also some affinity with the next group, especially in the absence of spurs and the size of the hind-toe.

The *Peacock* is a native of the forests of India. Its beautiful tail, or rather train (for the proper tail exists

Peacock.

underneath), has made this bird a favourite in the ornamental grounds connected with English country mansions. Alexander the Great found the peacock flying in great numbers in India, and introduced it into Europe, where at first it was shewn for money as a curiosity. The plumage of the *Impeyan*, also a native of the north of India, resembles that of the humming-birds upon a large scale; it can only be compared to the most refulgent hues of variously coloured and finely polished metals.

Our well-known domestic poultry, the *Common Cock* and *Hen*, are supposed to have originated in the Indian Archipelago, and to have been introduced at a still earlier period into Europe. Their usefulness and general habits are too familiar to require description. The *Turkeys* are the only representatives of this group in the New World, whence they were brought by the early discoverers, and are now quite naturalised in Europe. A more splendid species than the common one has been subsequently discovered in the Bay of Honduras. The *Guinea-fowl* is originally a native of Africa, where it lives in large flocks, in the neighbourhood of marshes. Its noisy and querulous disposition renders it troublesome in poultry-yards, although its flesh is excellent.

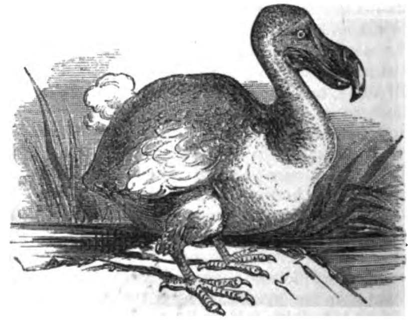
With this family must be classed a genus of birds recently discovered in Australia, and named *Megapodidæ*, on account of the size of their feet. These birds equal the turkey in size, are adorned with a crest, and have strong rasorial claws. According to Mr Gould, they do not incubate, but deposit their eggs in mounds composed of earth and vegetable matter, and by the natural heat engendered in these masses the eggs are hatched.

The *Curassows* (*Cracidæ*), which are restricted to America, are distinguished by the hind-toe being so much developed as to give some power of perching. They offer a remarkable contrast, in their plain colours, to the brilliant plumage of the Asiatic races, which occur in nearly the same parallels of latitude. They are equally capable of domestication with the fowls; and their flesh is of excellent quality. The *Curassows* are about the size of a turkey, and are handsome birds, having the head adorned with crests of long, narrow, erectable feathers, curled at the tips. They commonly perch upon trees. The *Guans* are still more arboreal in their habits. So many varieties of colour are found among them, that it is difficult to trace the limits of the different species. The *Hoazin* is a South American bird, which derives its subsistence almost exclusively from foliage, and chiefly from the leaves of a species of arum growing in marshy places. The toes, unlike those of all other gallinaceous birds, are destitute of any connecting membrane.

The *Tetraonidæ* (Partridge or Grouse tribe) are all of them wild birds, inhabiting uncultivated grounds in the colder climates of Europe, Asia, and North America. They are distinguished by a short hind-toe, a short tail, and comparatively dull plumage. The grouse, black-cock, and ptarmigan, abound in the Highlands of Scotland; and as the objects of a favourite amusement, give a value to much ground which would otherwise be nearly useless. They feed chiefly on the seeds of wild-plants. The largest species of grouse is the *Capercailzie*, or *Cock of the Woods*, once abundant in Scotland, and still so in Norway. It feeds on pine-shoots, and grows to the size of a turkey. Nearly all the grouse have the toes and legs more or less covered with soft feathers—a character which disappears in the *Partridges*, an extensive group, scattered in nearly all parts of the Old World, but unknown in the New. In the *Quails*, we have the miniature resemblance of partridges, but the tail is so short as to be nearly imperceptible. There is in tropical America a singular race of birds, called *Tinamous* by the Brazilians; they have scarcely any tail; the body is thick, and the whole appearance reminds us of a pigmy bustard. These birds live among herbage, and feed upon fruits and insects. Their flesh forms an excellent article of food.

The family of *Columbidæ*, containing a large number of elegant and lovely birds, appears much isolated from the rest, being rather adapted for perching than for scraping. Although it is particularly numerous, and spread over every part of the world, there is no difficulty in distinguishing its members from all other birds. One of their chief peculiarities is the *double* dilatation of the crop, which expands on each side of the gullet; and the young are fed with grain disgorged from this receptacle by the parent, and impregnated with a secretion which it forms. These birds live invariably in pairs; they nestle in trees or in the holes of rocks, and lay but few eggs, though they breed often. This family includes the whole of the well-known tribe of *Pigeons* and *Doves*. Some of the tropical species are of considerable size, and of very rich plumage. The *Common Dovecot-pigeon* is probably derived from the *Rock-pigeon*, which naturally breeds principally among the sea-cliffs, and but sparingly inland. But the *Ringed-pigeon* is of a different stock; and though it chiefly frequents the districts cultivated by man, it resists his nearer approach. The *Carrier-pigeon* is not a distinct species, but only a variety of the common one which has undergone a particular training; and it is probable that other varieties might be similarly trained.

It is proper here to notice an extinct species of fowl which has attracted much of the attention of naturalists,



Supposed form of the Dodo.

and is now believed to have been allied to the pigeon tribe. The *Dodo* existed in the island of Mauritius till

the time of Charles II., and we only know of it now from the descriptions of voyagers, and certain fragments which have happened to be preserved. It was a bulky bird, of heavy figure, with imperfect wings, and only a small bunch of feathers in the usual situation of the tail; a large, strong, curved beak; and legs and feet like those of a turkey. It is supposed to have been particularly adapted to feed on the nuts and seeds of the great forests in which it lived. Mr Strickland considers it as having been, in its mature form, very much like what other birds are in their early state—as it were 'a permanent nestling, covered with down instead of feathers, and with the wings and tail so short, as to be utterly unsubservient to flight.'

Raptores.

In strong contrast to the gentle and vegetable-feeding rasorial tribes is the ORDER RAPTORES, birds designed to subsist entirely on the weaker animals of their own and other tribes, and therefore generally large and powerful, with a formidable armature, consisting of a strong hooked beak, and talons more or less retractile. Such of this order as are designed to catch living prey, are also of great strength and swiftness of flight. Contrary to the usual rule, the female is larger than the male. The raptorial tribes, as compared with others, are not numerous, either as species or individuals; they form pairs, live solitarily, and do not breed large families. They may be arranged in three groups—the Falcons, Vultures, and Owls.

The *Falconidæ* (Falcon tribe) exhibit the perfection of the order, and correspond very closely in their general habits, and the adaptations of structure, with the feline tribe among the Carnivora. Their bodies are of moderate size; their forms light but powerful; their flight graceful; and their courage very great. They are technically distinguished from the vultures by a notch or tooth on the upper mandible, and by the acuteness and strong curve of their talons, which, like those of the cat tribe, are retractile. The members of this family are almost universally diffused over the earth's surface, some species of them existing wherever there is a sufficient expanse of land to supply them with food. Their plumage is destitute of a bright or gay assemblage of colours, but is nevertheless in many instances peculiarly elegant. The plumage of the young bird, however, is very different from that of the adult, which it is long in attaining; and when first hatched, the young falcon, like a new-born kitten, is blind and feeble.

The *Falconidæ* have been commonly divided into the *Noble* and *Ignoble;* the latter not being susceptible of training to the once noble sport of falconry. The Noble division comprehends the *Falcons Proper*, which are distinguished from the rest by the size of the tooth on the mandible, and by the power of their wings, which are long and pointed. They are the most courageous of all the family in proportion to their size, and are specially adapted to pursue and bring down their prey on the wing. From the peculiar construction of their wings, it is not easy for them to rise directly into the air; and their forward flight, in a calm state of the atmosphere, is very oblique. When they wish to rise directly, they fly against the wind, which raises them as it would a paper-kite. A large number of species are known in Europe. The Ignoble falcons have less powerful wings, which are shaped like those of the true falcons, with the tips obliquely cut off; the tooth on the bill is less strongly marked, and is often reduced to a mere festoon.

The *Eagles* may probably be considered as ranking next to the falcons. They are the largest and most powerful of the whole group, and pursue and destroy quadrupeds as well as birds. They are distinguished from all other Raptores by having the legs and feet feathered quite down to the toes. They usually build their nests in lofty and secluded situations, especially among mountains and precipices, and resist with great courage any attack upon their young. A large number

Golden Eagle.

of species, varying considerably in size, exist in Europe, and many others in America. Some of the English ones are no larger than the buzzards, which are nearly allied to them, and may be regarded in their habits, as in their size, as eagles in miniature. They reside in forests, building high in trees, and descending from the top upon their prey. They destroy much game, and are an especial pest to rabbit-warrens.

The *Hawks* are also nearly allied to the falcons, and some of them have been employed in pursuit of game, upon which, however, they stoop obliquely, and not perpendicularly. The tooth on the bill is reduced to a kind of festoon, towards the middle of its margin, but the shape of the bill, in other respects, is the same as in the falcons, being short, high, and curved from the base; the wings are also more rounded, but not so much cut at the ends as those of the eagles. The *Kites* have comparatively short feet and feeble claws, and they are much less courageous than the rest of the family. They are distinguished by their long wings and forked tail, by which their flight is rendered swift and easy, but it is less powerful than that of other Raptores. The common kite of this country has the power of hovering, balanced on its wings, for a longer time than any other known bird. It principally feeds on reptiles.

A few species of this family—mostly included among the *Ospreys* and *Ernes*, both of which, but especially the last, are nearly allied to the eagle—are aquatic in their habits, living upon the sea-shore, and subsisting chiefly or exclusively upon fish. They are at once distinguished by the roughness of the under surface of the foot, which assists them in holding their slippery prey; and the Ospreys are also able to turn backwards the outer toe, and oppose it to the rest, so as much to increase the grasping power of the foot.

The Genus *Circina* (Harriers) have a facial ruff, the feathers of which approach in structure to those of the owls. Three species are found in Britain—the Ring-tailed Harrier, Montagu's Harrier, and the Moor or Marsh Harrier.

Family *Strigidæ* (Owls) fulfil during the night the same office which the bolder hunting-falcons perform in the open day, and serve to keep in check the numbers of

those small mammals to which nature has also allotted a nightly season. They also take birds from their nests, or snatch them from their roosting-place. For their mode of life, which is chiefly nocturnal, their organs are perfectly adapted. Their eyes are so formed as to perceive an object even amidst the gloom of night; their ears are calculated to collect and concentrate the faintest undulations of sound; and their wings are constructed for a noiseless flight, so that they steal unheard upon their prey. In the daytime, they occupy the dark recesses of the forest, wooded rocks, and ivy-mantled towers. Owls, in ancient times, from their appearance of imperturbable gravity, were regarded by some as the emblems of Wisdom. The Egyptians represented Minerva under the form of an owl; and the coin of the Athenians, who considered themselves under the especial protection of that goddess, was stamped with its image. This family consists of only one genus, *Strix*, which is usually divided into two sections—Horned or Eared Owls, and Smooth-headed Owls; the former having a tuft of long feathers on each side of the forehead, and the latter being destitute of those appendages.

The *Great Eagle Owl* (*S. bubo*) furnishes an example of the Horned Owl. It is the largest of the tribe, being nearly two feet in length, and from five to six in the expanse of its wings. It is chiefly an inhabitant of the mountainous districts of Northern Europe, but is seldom seen in Britain. It is destructive to grouse, hares, and fawns. This species builds on rocks or on lofty trees.

Of the Smooth-headed species, the *Barn Owl* (*S. flammea*) may be given as an example. It is more common in this country than any other kind of owl. Its food consists chiefly of mice and small birds, which it swallows whole, without any attempt to tear them in pieces with its claws. The bones and other indigestible parts are afterwards disgorged in small pellets.

Barn Owl.

Family *Vulturidæ* (Vultures) are characterised by a long, straight, and slender beak, curved only at the extremity, and by having a greater or less proportion of the head and sometimes of the neck denuded of feathers. The power of their claws does not correspond with the bulk of their body. Their food consists chiefly of dead carcasses and offal, with which they often gorge themselves to such a degree that they are reduced to a state of stupidity. In hot latitudes, where they chiefly abound, they are of great service in consuming putrefying bodies, which would otherwise infect the air, and spread pestilence in the neighbourhood. No sooner is an animal dead, than its carcass is surrounded by numbers of these birds, which suddenly appear, coming from all quarters, in situations where not one had just before been seen. In some towns of America, they are kept in the market-places, to devour and clear away the offal; and in India, penalties are inflicted on their disturbers.

This family consists of five genera—Gypætus, Vulture Proper, Sarcoramphus, Gypogéranus, and Percnopterus, severally represented by the Lamb Vulture, the Griffon, the Condor, the Secretary Vulture, and the Neophron, which are the only species we shall notice.

The *Lamb Vulture* (*Gypætus barbatus*), or *Bearded Vulture*, the largest of the European birds of prey, measures upwards of four feet from beak to tail, and nine or ten feet in the expanse of its wings. This species, which is the *Lammergeyer* of the Swiss and German Alps, closely resembles the eagle in appearance as well as habits. It has the same confident and upright bearing, and it seeks a living prey as readily as carrion.

Lammergeyer.

The *Griffon* (*Golden Vulture*, or *V. cinereus*) is common in the Alps and Pyrenees, and species of it are found in all the mountainous regions of Africa and of Southern Asia. It nearly equals the Lamb Vulture in size, and is similar to it in habits.

Sarcoramphus (the Condor), the king of the vulture tribe, is peculiar to the Andes. The extent of its wings when expanded is from ten to twelve feet. Borne on these wide-spread pinions, the *Condor* ascends higher than any other bird, being sometimes found at an elevation of 10,000 or 15,000 feet above the level of the ocean.

Secretary.

Gypogéranus (the Common Secretary Vulture), in the

lengthening of its legs and neck, together with its short and strong talons, presents a conformation adapted to destroy and devour poisonous reptiles, upon which it chiefly subsists, although it does not reject lizards or insects. Species of this vulture inhabit the Cape of Good Hope, the Gambia Coast, and the Philippine Islands. It has been called the *Secretary* from the feathers at its ear presenting the appearance of a pen.

The *Neophron Percnopterus* is common in the northern parts of Africa. In Egypt, it is called by Europeans *Pharaoh's Hen.* The species of this vulture, which are of comparatively small size, subsist entirely upon carrion.

Inseasores.

ORDER INSESSORES (*Perching-birds*) comprehends an immense number of species, which spend a large portion of their time on the wing, but at intervals rest on trees or elsewhere, possessing therefore short and slender legs, with feet fitted generally by three long fore-claws, and a hind one to clasp any slender object. They are, generally speaking, mixed feeders; some, however, being more given to animal food than others, and furnished accordingly with bills and claws more allied to those of the Raptores. Many are distinguished by their finely coloured plumage; others, by their powers of singing; and there are some which display a surprising sagacity, with singular powers of imitation. As a rule, the females are smaller, less brilliant in plumage, and less melodious than the males.

The Perching-birds are divided into four groups, each distinguished by some noted external feature connected with their habits.

Group *Conirostres*, so called from having a simple conical beak, may be considered as typical of the order, being the most miscellaneous feeders. Their feet, moreover, are adapted for the greatest variety of purposes, being equally well fitted for walking the ground as for grasping the branches of trees. The group is constituted of five families—Crows, Starlings, Finches, Hornbills, and Crossbills.

Family *Corvidæ.*—Of this, the *Common Crows* are the most characteristic examples, as they combine the general characters of the class in a greater degree than any other birds. In every climate habitable by man these birds are found; they are constructed for powerful and continued flight, as well as for walking firmly upon the earth; they feed indiscriminately on animals or vegetables, and when pressed by hunger, do not refuse carrion; their smell is remarkably acute. They are bold but wary, live in common societies, and possess great courage: when domesticated, they possess a power of imitating the human voice nearly equal to that of the parrot; and, like it, shew signs of greater intelligence than is found in the rest of the class. Under the general term *Crow* are included the *Raven*, which is the largest of European perching-birds, and which is bold enough occasionally to carry off poultry; the *Corby Crow*, which is very destructive to eggs and young game; the *Rook*, which chiefly feeds on insects, and especially devours the grubs of the coleoptera, though it occasionally eats grain if its proper food be scarce; the *Hooded Crow*, which feeds upon mollusks, &c., on the sea-shore; and the *Jackdaw.* The last is a familiar bird, inhabiting deserted buildings, steeples, and high towers, and easily tamed, but troublesome on account of its propensity to secrete any small article of value that comes in its way. The *Magpies* are nearly allied to the Crows; as are also the *Jays*, which live principally, however, in woods, and feed on acorns, &c. The *Nutcrackers* also belong to this family; their habits in many respects resemble those of the woodpeckers; they climb trees, and perforate their bark, and devour all sorts of fruits and insects, as well as small birds.

The *Sturnidæ* are best known by the *European Starling;* the family seems like a smaller race of crows, which they nearly resemble in manners and structure, while much weaker. They seek their food generally upon the ground, are social in their habits, and seem to prefer plains frequented by cattle, on the parasites of which animals they love to feed. They are easily tamed, and may be taught to speak, or to imitate the song of other birds. A great number of species, in different parts of the world, are referred to this family; amongst them may be specially noticed the *Icterinæ*, or *Hangnests* of South America, which build long purse-shaped nests, suspended from the slender branches of lofty trees, in order, as is understood, to save their young from becoming the prey of serpents; they feed on fruits and beetles, and are never seen upon the ground. The African *Buphaga*, or *Ox-pecker*, is also remarkable for its habit of perching upon the backs of cattle, to which it clings by its sharp claws, compressing the skin, to force out the larvæ of gadflies, &c., on which it feeds.

The *Fringillidæ* (Finches) are the smallest of this group of Perching-birds, and are readily known by the shortness and strength of their conical bills. They subsist generally on grain. The number of species is very great; and some among them are everywhere diffused. The *Sparrow*, for example, is in this country found wherever there is a human habitation, generally building its nest under our eaves, and feeding either upon our grain-fields, or on the crumbs that fall from our tables. The Chaffinches, Linnets, Goldfinches, Bullfinches, and

Goldfinch.

Larks, are other species of the Fringillidæ well known in this country. To the same genus with the linnet belongs the *Canary-bird*, originally brought from the Canary Islands, but now so abundantly bred in captivity, that it is difficult to assign the original colour from the numerous varieties that present themselves. The *Chaffinch* is a bird of cold climates: one species, known as the *Brambling*, visits Britain only in the winter; and another nestles in the high Alps, and descends only in the depth of winter to the secondary ranges. To this family belong the *Weaver-birds* of tropical climates, which are celebrated for the remarkable construction of their nests, composed of blades of grass interwoven together; in one species, a number of individuals unite their nests into a large single mass, divided into numerous compartments. The *Whidas*, or *Widow-birds*, resemble the linnets; but have a remarkable development of feathers in the tail at the breeding-season, being destitute of it at other times. The *Grosbeaks*, of which one British species is known as the *Greenfinch*, are remarkable for the thickness of their beaks, which are exactly conical, and with which they pick out the kernels on which they feed. The *Virginian Nightingale* is nearly allied to the grosbeak. To this family also belong the *Buntings*, granivorous birds, of which several species have been seen in Britain; and the *Larks*, so well known for their habit of continuing their song whilst ascending to great heights in the air. With the exception

of one species, these last are peculiar to the Eastern Hemisphere. The hind-toe, and the claw which terminates it, are greatly prolonged; the feet are altogether formed for walking on the ground, where, indeed, these birds construct their nests.

The *Buceridæ* (Hornbills) are birds of the Old World, resembling crows in most respects, but distinguished by the peculiarity from which they take their name—namely, a huge excrescence upon the upper beak, not solid, except in one species, but composed of a fragile net-work of bony fibres. The use of this curious appendage is unknown.

The *Loxiadæ* (Crossbills) are distinguished by a strong curvature of the mandibles, causing their tips to pass each other—a peculiarity which gives them a great advantage in extracting their favourite food, the seeds of the pine-cones.

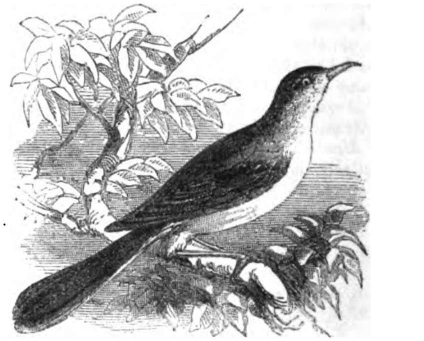
Group *Dentirostres* embraces an extensive variety of genera, all characterised by their more or less carnivorous habits, and the presence of a notch, called a tooth, upon the upper mandible, designed to serve for killing—the peculiarity from which the name of the group is derived. The mouth is, moreover, protected on each side by bristles, which defend the soft parts during the struggles of the prey. The group is divided into five families—Shrikes, Fly-catchers, Thrushes, Warblers, and Chatterers; the first two of which are the most addicted to preying habits, while the last are comparatively vegetable feeders.

The *Shrikes*, *Laniadæ* (from *lanius*, a butcher), are the typical family of the *Dentirostres*. They kill their prey, which consists chiefly of small birds, mice, shrews, and frogs, by repeated blows of the bill on the head; and after satisfying their hunger, they hang up what remains on a thorn, to be devoured at their leisure. From this habit, they have obtained the name of *Butcher-bird*. They are about the size of a black-bird, are gregarious in their habits, and their flight is irregular and precipitate.

The *Fly-catchers*, *Todidæ*, or *Muscicapidæ* (from *musca*, a fly, and *capio*, I take), are characterised by a depressed beak, armed with bristles at the base. They are generally migratory, as all fly-catchers must be, to obtain their food. The two following species only are recognised as visiting Britain:—The *Red Fly-catcher* or *Red Finch* (*M. atricapilla*) visits England in the summer months. Its length is about five inches, and the extent of its wings eight. The *Gray-spotted Fly-catcher* (*M. grisola*) is common enough in England, but rarely visits Scotland. This species arrives early in May, and frequents plantations, orchards, and gardens. When watching for its prey, it sits on one of the outer branches of a tree, from which it descends upon a passing insect, regaining immediately its station.

Of the *Thrushes* (*Merulidæ*), the *Black-bird* (*Turdus merula*) may serve as the type; it is about eleven inches in length. Its food consists of fruit, insects, and caterpillars. The male Black-bird has a glossy black plumage, while the upper part of the body of the female is of a blackish brown; the bill being of an orange-yellow colour, and the feet brown. This beautiful and well-known songster is among the first to welcome the return of spring.

The *Common Thrush* (Mavis or Song-thrush) and *Fieldfare* are also well known and characteristic examples. These, as well as the *Missel-thrush*, *Red-wing*, *Ring-thrush*, &c., are closely allied species of the same genus, of which the other species are distributed over the whole globe. The *Mocking-birds*, on the other hand, which probably stand unrivalled for their powers of voice, and have the singular gift of imitating the cries of many other birds, are restricted to America: some of them approximate to the shrikes in their habits. The *Orioles* are also nearly allied to the thrushes; they are migratory birds, having longer wings than their congeners, and chiefly frequent the south of Europe, where they build very curious hanging-nests. A few



Mocking-bird.

species of this family have somewhat aquatic habits. One of these is the *Dipper*, or *Water-ousel*, which immerses its whole body without swimming, and walks about in a jerking, fluttering manner at the bottom of streams, in search of the small animals which constitute its food.

The *Warblers* (*Sylviadæ*) are the most musical of European birds, but are inferior to many others in the brightness of their colours. Those best known are the Nightingale, the Redbreast, and the Willow Wren.

The *Nightingale* (*Sylvia luscinia*) is a migratory bird, which visits England in the beginning of April, and leaves it in August, rarely getting so far north as Scotland. It builds on trees, and does not sing till the young ones are hatched. The notes which it then gives forth have in all ages been a theme of admiration. 'To hear it on one of those balmy mornings in May, when every leaf is freshness and every breath young perfume, is worth more than a whole musical festival.' The Nightingale is the largest of the Warblers, its length being about seven inches, and the extent of its wings ten or eleven inches.

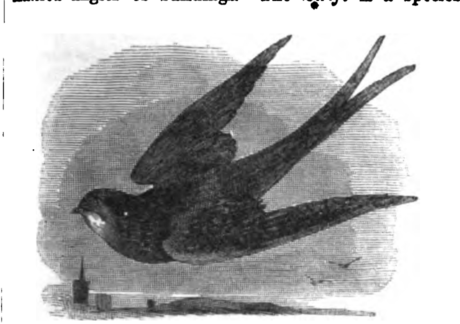
The *Robin* (*S. rubecula*) is a constant inhabitant of Britain, and the greater part of the European continent. It is a beautiful little bird, and has a sweet song. It is useful in gardens and orchards, as its food consists principally of worms and caterpillars. In summer it is shy, but in winter it draws near the abodes of man. The *Wagtail* (*Motacilla*) is another member of this family which attracts general attention, on account of the habit from which it derives its name, and its sprightly movements, as it flits about searching for insects near shallow waters.

The *Chatterers*, *Ampelidæ* (ἄμπελος, a vine), are characterised by a straight convex beak, and an uncommon width of gape. The *Bohemian Chatterer*, or *Wax-wing*, is a species well known in Europe, Asia, and America. It is less than a thrush, and is crested on the head. Its general colour is a vinish gray, with a black throat.

The group *Fissirostres* derive that name from having the beak deeply cleft—a peculiarity which gives a wide gape, and fits these birds for catching insects on the wing. Some have the outer toe nearly as long as the middle one, and were hence called by Cuvier *Syndactyli*.

The family *Hirundinidæ* (Swallows) are well-known summer visitors of the British Islands, Africa being understood to be their chief winter resort. They are remarkable for being so much on the wing in search of food, and for their vivid, irregular movements in flying. The hind-toe is directed very much forward, and all the four are armed with strong claws, giving

the animal the power of clinging to the faces of perpendicular rocks and buildings. The *Martin* is a familiar bird, building a curious mud-nest in the sheltered angles of buildings. The *Swift* is a species



Swift.

possessing more enduring powers of flight than the swallow, which is often seen on its long journeys to fall wearied upon the surface of the sea. In the Indian Archipelago is a small species of swallow, which forms its nest of a kind of sea-weed, which it macerates in its stomach, and arranges in layers. These nests are used in China to make a kind of soup, much prized as a delicacy.

The *Goat-suckers*, or *Night Jars* (*Caprimulgidæ*), fly in the dusk, and feed on moths and beetles, which they seize on the wing. Like the owls, they cannot bear the glare of day. In Britain, we have only one species, which visits in the beginning of summer, and leaves us in the end of September. It is chiefly found on furze of commons, wild bushy heaths, and broken hilly ground,

Goat-sucker.

covered with ferns, especially in the neighbourhood of thickets and woods. It is about eleven inches in length, and twenty-three in the expanse of its wings. It derives its name from the absurd belief of the ancients, that it injured the teats of goats in its attempts to suck them.

The *Bee-eaters* (*Meropidæ*) are said to be extensively distributed in Africa, where they migrate in small flocks to the countries along the northern shores of the Mediterranean. They feed on insects, especially bees, which they pursue much in the manner of swallows. To this family also belong the *Rollers*, most of which are natives of the East, but of which one species inhabits Europe. They are in some respects intermediate between the swallows and bee-eaters. One species is stated to perch and watch for prey on the horn of the rhinoceros, giving notice to that animal of the approach of the hunter.

The *King-fishers* (*Halcyonidæ*) are generally natives of the warmer regions of the globe. They live upon aquatic insects and small fish, and may be seen perching on the stump of some decayed tree which overhangs a stream, watching the minnows, on which they dart with

King-fisher.

unerring aim. They then return to their perch, beat their victim to death, and swallow it. The only species indigenous to Britain is a beautiful little bird, rather larger than the lark. The *Todies* (*Todidæ*) are small American birds, nearly allied to the former family.

The group of *Climbing-birds* (*Scansores*) comprehends four families of considerably diverse character, but having one remarkable peculiarity in common—namely, an arrangement of the toes, by which two are directed forward and two backward, so as to fit the bird especially for climbing. They are not good walkers or fliers, and, careless of nest-building, are content to rear their young in the hollows of trees. It may be said that of all birds they are the most arboreal.

Family *Picidæ* (Woodpeckers).—This kind of bird is well fitted for climbing trees, not only by its *zygodactyle* feet, but by the pointed feathers of its tail, which, being inserted in the bark, form a rest for it as it ascends. It is furnished with a long sharp tongue, which it inserts into the chinks of timber in search of insects, transfixing them with its barbed point, and further securing them by means of a viscid substance with which it is covered. At the pairing-season, the Woodpecker communicates with its mate, not by song, as is customary, but by rattling its beak against a dead-branch; from which sound its name has been derived. There are three species constantly resident in Britain—the Green Woodpecker, the Great-spotted Woodpecker, and the Lesser-spotted Woodpecker. The first is sometimes called the *Rain-bird*, because it makes more noise than usual before wet weather. This bird is about thirteen inches in length, and twenty-one in breadth.

The *Wryneck* (*Yunx torquilla*) belongs to this family. In England it is called the *Cuckoo's Messenger*, because it arrives only two or three days before that bird. Its food consists chiefly of ants. A hole in a tree is generally chosen for nestling.

The *Creepers* (*Certhiadæ*).—Of these birds, the *Nuthatch* is the only species known in Europe. It is frequently seen during the day running rapidly about, either up or down the trunk or branches of a lofty oak or beech tree. The food of the Nuthatch consists of insects and seeds, also acorns and nuts. It procures a supply of insects, such as earwigs and caterpillars, from beneath the old bark of trees, by lifting it up with its wedge-shaped bill. It is remarkable for its instinct in fixing a nut in a chink, while it pierces it with its bill, swinging the whole body as on a pivot to give effect to each stroke.

The *Cuckoos* (*Cuculidæ*).—The *Common Cuckoo* (*Cuculus canorus*) is the type. It is a migratory bird, arriving in this country about the end of April. Its cry, 'cuckoo,' from which it derives its name, is well known. In size, the bird is nearly equal to a pigeon, and is of an ash-gray colour. Its food consists of caterpillars,

insects, and small fruit. The Cuckoo has no nest of its own, nor does it hatch its own eggs, but deposits them

Cuckoo.

in the nests of other birds, such as the Hedge-sparrow, by which they are reared; and as it deposits but one egg in each nest, the process of rearing the progeny may be carried on by several foster-parents at once. In its flight, it is usually attended by small birds, chiefly the Meadow-pipits.

The *Toucans* (*Ramphastidæ*) have bills of enormous size, nearly as large as the body itself. They are gregarious in their habits. Their food consists of fruit and insects, and the eggs and young of other birds. In feeding, they throw each morsel into the air, and catch it in its descent. This family is peculiar to the warm regions of America. They are in general black, with lively colours on the throat, breast, and croup.

The *Psittacidæ* (Parrots) constitute a family which is very widely diffused through the torrid zone in both new and old continents, and is scarcely found beyond it. It contains a large number of species, each of which has its peculiar locality, the short wings of these birds not enabling them to traverse large tracts of sea. They correspond with the other *Scansores* in little else than the structure of the foot, and this is formed rather for grasping than for climbing. It is also used for conveying food to the mouth, a peculiarity nowhere else seen but in the goat-suckers. Their beak is stout, hard, and solid, curved and pointed very much as in the diurnal birds of prey. Their jaws are set in motion by a greater variety of muscles than are found in other birds. The tongue is thick, fleshy, and rounded; and the larynx, or organ of voice, is also more complicated—by which peculiarities they gain their facility of imitating the human voice as well as other sounds. Their voice in a state of nature, however, is loud and harsh. They use their crooked bills in clambering up trees, and nestle in hollow trunks. They subsist upon the succulent parts of vegetables, especially bulbs and fruits. They are distinguished from the rest of the scansorial birds by their intelligence and docility—qualities in which some species are unsurpassed by any members of the class.

The *Parrot tribe*, nearly all of which are adorned with gorgeous colours, has been divided, chiefly from a regard to peculiarities of plumage, into many minor groups, the limits of which, however, are mostly arbitrary. The *True Parrots* are square-tailed, and have no crests. They are found in both the old and new continents, and are more easily taught to speak than others of the family. The *Cockatoos* are also square-tailed, but have crests upon their heads. The white ones inhabit the Indian Archipelago and Australia; they are singularly gentle and affectionate, and easily maintained in captivity in Europe. The *Love-birds* are a beautiful group, found in both continents, nearly allied to the parrots, but of diminutive size. The *Parroquets* have a long-pointed tail, and chiefly inhabit the Asiatic continent and islands, and Australia. An American species of Parroquet is the only member of the parrot tribe found to the northward of the Tropic of Cancer. The *Macaws* are long-tailed American species, which exceed all the rest in size, and are superbly coloured. The *Loris*

Cockatoos.

are Oriental species, with square tails and dense soft plumage, the colours of which are glowing in the highest degree; the beak is in general comparatively feeble, and they feed upon the juices of flowers and the pulp of the softest fruits.

The group TENUIROSTRES (Slender-billed Birds) are generally of small size and great beauty of plumage, chiefly confined to tropical countries. By their slender beaks and long tongue, forked or divided into filaments at the extremity, they are specially fitted to live upon the juices of flowers; in which respect, as well as in their fine colouring, they remind us of certain families of insects. Many of them, however, are also insectivorous. The feet are very short and delicate.

The *Meliphagidæ* (Honey-suckers) are distinguished by their notched bill; their tongue is terminated by a bunch of delicate filaments; and the hind-toe is so strong and robust, that it serves as a support to the bird during the process of feeding. This group is chiefly confined to Australia, where its members abound in great variety of form, and where they find a never-failing support in the luxuriant vegetation of that country.

The *Paradisidæ* (Birds of Paradise) are among the largest of the *Tenuirostres*, and seem to live, like the

Bird of Paradise.

rest of the order, chiefly upon soft vegetable substances. They are confined to New Guinea and the neighbouring

islands; and for a long time no specimens were obtained but such as had been deprived by the natives of their legs, whence it was at one time supposed that they were destitute of limbs, and supported themselves entirely on their airy plumes. The extraordinary development of their feathery appendages is well known; but of the purpose these serve in their economy, no plausible account has been given. The very restricted locality of these birds, and the savageness of the people who inhabit it, have prevented naturalists from obtaining much knowledge of their habits. They are partly supported upon insects.

The *Trochilidæ* (Humming-bird tribe), so celebrated for the metallic lustre of their plumage, and particularly for the gem-like brilliancy of some of their feathers, have within their long slender beak a tongue divided almost to the base into two filaments or threads. These filaments are *not* tubular, as sometimes described, but flattened. The organ is employed for diving into flowers and sucking their juices; but it is not improbable that it also serves for catching insects, since it is unquestionable that, like others of the order, the Humming-birds are partly insectivorous. When hovering over flowers, these birds balance themselves in the air by a rapid motion of the wings, and it is by this movement that the *humming* sound is produced from which they take their name. The flight of these birds, the smallest of the order, is so rapid as frequently to elude the eye. They live solitarily; defend their nests with courage, attacking with their needle-like bills the eyes of intruders, which makes these minute creatures truly formidable; and they fight with each other desperately.

This family is exclusively confined to America, and, with few exceptions, to the southern part of that continent and the adjacent West Indian islands. More than 170 species are at present known, and others are constantly being discovered. The smallest of them, when plucked, is less than a large humble-bee; and one only, which is much larger than any others as yet known, nearly equals the common swift in size.

The *Cinnyridæ* (Sun-birds) represent the Humming-birds in the eastern continent. They are closely allied to the *Trochilidæ* in general structure, and in the mode of obtaining their food, but their tongue is not so deeply divided. They are small birds, and the males have the most brilliant colours, rivalling those of the humming-birds during the breeding season; but the garb of the female, and of the male at other parts of the year, is much more dull. The bill is not so straight as in the Trochilidæ, and the legs less delicate, so that a connection between that and other families is evident through this one. The *Sun-birds* are of a lively disposition, and sing agreeably.

Hoopoe.

The *Promeropidæ* (Hoopoes) are also restricted to the Old World; one species, the *Common Hoopoe*, annually visits Europe in company with the Bee-eaters, and other swallow-like birds; but, unlike its congeners, it seeks its food on the ground. Most of the tribe, however, feed upon the juices of flowers and succulent fruits, and their plumage possesses metallic lustre. The feet, as well as the tongue, are very short.

CLASS MAMMALIA, OR SUCK-GIVING ANIMALS.

The MAMMALIA agree with birds in possessing a complete double circulation and warm blood; and with reptiles in breathing air, and generally living on the surface of the earth; but they differ from all other vertebrata, not so much in producing their young alive (which is the case in a few species of reptiles and fishes), as in their subsequent nourishment of them by suckling—from which circumstance the name is derived. This class is placed at the head of the Animal Kingdom, not only as being the one to which Man belongs, but also because it is that which enjoys the most numerous faculties, the most delicate sensations, the most varied powers of motion; and in which all the different faculties seem combined to produce a more perfect degree of intelligence; the one most fertile in resources, most susceptible of perfection, and least the slave of instinct. Although principally adapted to motion on the ground, we find one tribe possessed of the power of rising into the air like birds, and another formed to inhabit the water like fishes; but both these agree with other Mammalia in all essential characters, and differ very widely from the classes with which their habits seem to associate them. To the Mammalia is confined the protection of the body by hair or fur; the nearest approach to it being in the hair-like feathers of a few species of birds. But the presence of this covering is by no means universal in the Mammalia.

Naturalists, in seeking to classify the Mammalia, have to look chiefly to those indications which the teeth, extremities, and other external characters furnish, regarding the general habits and dispositions of the several animals. Thus, keeping out of view minor distinctions, the possession of sharp fangs and claws is a clear mark of carnivorous habits; flat-topped teeth and hoofs, equally a proof of a gentle and herbivorous character. The flapper of the whale shews a fitness for progression in the sea; the development of a wing on the hand of the bat, a design that the animal should make its way through the air. Other distinctions are found in the advance of the animals in their general development, forming still broader grounds of classification.

A minor portion of the Mammalia produce their young in an immature state—indeed scarcely alive—and these attain a comparatively low permanent condition, their bodily structure presenting many points of affinity to birds and reptiles. In this division, which are chiefly localised in Australia, there are two groups.

Monotremata.

The MONOTREMATA—so named because, as in birds, the excretory openings are united into one—are exclusively Australian. There are two species, the *Echidna*, or Spiny Ant-eater, and the *Ornithorhynchus*, or Duck-billed Platypus.

The *Spiny Ant-eater* (*E. hystrix*) is rather larger than the common hedgehog, to which it bears some resemblance, being armed with spines on the upper part of the body, and having a prolonged snout. It frequents sandy places, and burrows in the ground. Its food consists of ants and other insects, which it entraps with its long and adhesive tongue. The Ornithorhynchus derives this name, now universally adopted by naturalists, from the bird-like snout of the animal (ὄρνις, a bird, and ῥύγχος, a beak). 'The similarity of its jaws to those of a bird,' says Swainson, 'is so great, that

upon its first discovery, it was strongly suspected the specimen sent to Europe was a deception, practised by some cunning fellow on the credulity of naturalists by

Ornithorhynchus.

ingrafting the bill of a duck upon the skull of a quadruped.' By the colonists, it is called the Water-mole—an appellation suggested by its aquatic habits, combined with some slight resemblance which it bears to the common European mole. The ornithorhynchus is about eighteen inches in length, and clothed with a dense fur. It frequents the tranquil parts of rivers, in the banks of which it burrows, and it obtains its food by the capture of small aquatic animals.

Marsupialia.

The MARSUPIALIA exhibit a nearer approach to the full mammalian character. The name, signifying Pouched Animals (Lat. *Marsupium*, a purse), is derived from the remarkable provision which is made for the continued nourishment of the young after their immature birth. The new-born imperfect offspring attaches itself to the teats of the parent, and remains fixed there until it has acquired a degree of development comparable to that with which other animals are born. The skin of the abdomen of the parent is so disposed as to form a pouch, in which these imperfect young are protected, and into which, long after they can walk, they retire for shelter on the apprehension of danger. It is remarkable that, notwithstanding the general, and usually very striking, resemblance of the species to each other, they differ as much in the teeth, the digestive organs, and the feet, as do the other orders of Mammalia from each other; and indeed it may be said that some of these other orders are *represented* each by a strongly analogous group, in the Marsupialia.

The geographic range of this order is extremely peculiar. With the exception of the Opossums, which inhabit America, its species are at present almost confined to Australia and the neighbouring countries, where they constitute, with the Monotremata, almost the only mammiferous animals. It is remarkable also, that from the remains found in secondary rocks, they appear to have existed at a much earlier geological period than the superior Mammalia, and to have been more extensively diffused over the earth's surface than at present.

The *Marsupialia* may be divided into the following families, which have been named according to their predominating food. These terms must not, however, be regarded as strictly indicating the food of the several species contained in each group, but only their general tendency to select for their support the substances implied by those designations. 1. *Sarcophaga*, or Flesh-eaters, such as the *Dasyurus*. These have three kinds of teeth,* long canines, and a simple stomach like that of the Carnivora. 2. *Entomophaga*, or Insect-eaters, such as the *Opossum*. These have also three kinds of teeth and a simple stomach, but a more complex intestinal canal: they are parallel with the Insectivora. 3. *Carpophaga*, or Fruit-eaters, as the *Phalangers*, or Flying-opossums. These have large and long incisors in both jaws, the canines sometimes absent, and a more complicated intestinal canal. They may perhaps be regarded as representing the frugivorous Bats. 4. *Poephaga*, or Grass-eaters, as the *Kangaroos*. These have long anterior incisors, the canines only present in the upper jaw, or altogether wanting, and a complex intestinal canal like that of other herbivorous Mammalia. 5. *Rhizophaga*, or Root-eaters, as the *Wombat*. These, in the structure of the teeth and alimentary canal, are true Rodentia.

All the existing species of the first family, *Sarcophaga*, are confined to New Holland and Tasmania. These animals vary in size, from that of a small wolf to that of a mouse. The larger ones possess considerable ferocity, destroying sheep, and even invading houses; others attack poultry, of which they suck the blood; and the smallest are partly insectivorous, and live on trees, thus shewing an approach to the next family. The names *Hyæna*, *Devil*, *Wild-cat*, &c., applied by the colonists to these animals, sufficiently indicate their general correspondence in habit with those of the order Carnivora.

Of the second family, *Entomophaga*, some are adapted to live on the ground, and even to burrow beneath the surface, whilst others ascend trees in search of their food. To this latter group belongs the *Opossum* tribe, which is extensively diffused through America. These have a long and prehensile tail; and the hinder thumbs are long, and effectively opposable to the other digits. They are nocturnal animals, of slow gait, and nestle upon trees, where they pursue birds, insects, &c., without rejecting fruit. The *Virginian Opossum* is

Virginian Opossum.

nearly the size of a cat. It enters the villages at night, and attacks poultry, devouring also their eggs. One species frequents the marshes of the sea-coast, where it feeds chiefly on crabs. In a part of this tribe no pouch exists, but only a vestige of it, in the form of a fold of skin on each side of the abdomen. In these, the mother supports her young by entwining her tail with theirs.

The animals of the third family, *Carpophaga*, are peculiarly adapted to live among the trees on which they seek their food. Some species, in their general form, and in the prehensile character of their tails, approach the opossums. Such are the *Couscous* of the Molucca Islands; these feed on insects and fruit. At the sight of a man, they are said to suspend themselves by the tail; and if he gazes at them steadily for some time, they fall through lassitude. The most remarkable species is the *Petaurus* of New Holland, which much resembles the flying-squirrels. Like these, it possesses an extension of the skin on each side of the body, between the anterior

* The front-teeth are termed incisors, or cutters; those next to the incisors, are canine, or dog-teeth; and those at the sides of the jaws, molars, or grinders.

and posterior legs; and a flattened bushy tail, by the help of which it can take leaps of considerable length. Like the bats, or the flying lemur, to which it may be compared, it is a nocturnal animal, remaining during the day nestled in the hollows of trees; but it becomes animated as night advances, skimming through the air, supported by its lateral expansions, half leaping, half flying from branch to branch, and feeding upon leaves and insects. It would seem that, whilst in motion, it has some power of altering and directing its course. Another animal belonging to this group, the *Phascolarctos*, or *Koala*, a native of New Holland, is as large as a moderate-sized dog. It has the gait and carriage of a young bear, and passes its life upon trees, and in dens or holes which it hollows at their feet. The female carries her young for a long time on her back.

The family of *Poephaga* consists chiefly of the *Kangaroos* and the *Kangaroo-rat*, all of which are inhabitants of New Holland and the neighbouring countries. The Kangaroos are remarkable for the enormous length of their hinder feet, whence their generic name, *Macropus* (long-footed), is derived. The hind-legs and tail are also very largely developed; whilst the fore-legs and feet are very small. From this great inequality in the size of the limbs, they advance on all-fours very slowly; but they can make immense leaps with the hind-legs, the tail probably assisting them. These are furnished with one large nail, almost like a hoof, which is a powerful weapon of offence and defence; for, supporting itself upon one leg and its tail, the animal can inflict a very severe blow with the leg which is at liberty. The largest species is sometimes six feet in height, having the bulk of a sheep, and weighing 140 pounds. Its flesh is used as food by the New Hollanders, and is described as being somewhat like venison. The Kangaroo grazes, like ruminant animals, and is the only inhabitant of New Holland that at all represents that tribe. The young ones reside in the maternal pouch until they are able to graze for themselves, which they effect by stretching out the neck from their domicile while the mother herself is feeding. Several species exist, diminishing in size to less than that of a hare.

Great Kangaroo.

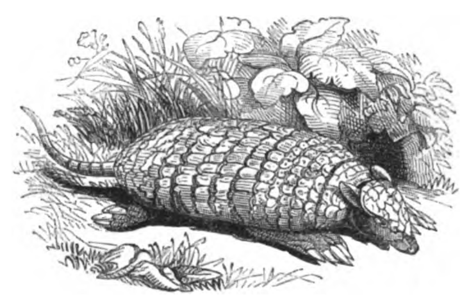
The Kangaroo-rat connects this family with the preceding one; it is about the size of a small rabbit.

The last family, *Rhizophaga*, contains only one species at present known—the *Phascolomys Wombat*. This animal is about the size of a badger, by which name it is known to the colonists, and is a native of Tasmania. It is a sluggish animal, with a flattened head and body. It burrows in the forests and low grounds; hiding itself in natural crevices at higher elevations. When attacked, it grunts like a pig; it bites hard, and is furious when much provoked. As already mentioned, the organisation of its digestive system corresponds closely with that of the Rodentia; and from what is known of its food, it seems to derive support, like the animals of that order, in the tougher kind of vegetable substances.

Another subdivision of the Mammalia is marked by higher characters than the preceding, but still must be placed in a position somewhat below the highest, the animals composing it being generally diminutive and weak, with a lower style of dentition, and less complex brain, than those which are next to be considered. In this division are comprised three orders—*Edentata*, *Insectivora*, and *Rodentia*.

Edentata.

ORDER EDENTATA take their name from the peculiarity common to all, of an entire absence of the incisor teeth. One large group, *Myrmecophaga*, or Ant-eaters, are specially fitted for their insectivorous mode of life, by the long-pointed form of their muzzle and the strength of their feet, the extremities of their toes being nearly included in large nails, which approach in character to hoofs. They are peculiar to the warm and temperate regions of South America. Some species are covered with hair; others with scales, which they elevate when irritated. They possess a long thread-like tongue, always covered with a gluey saliva, and which forms an admirable instrument for catching burrowing insects such as ants. Another group, the *Armadillos*, are remarkable for the dense armour of hard scales



Armadillo.

with which they are covered. They subsist partly on vegetables, and partly on insects and carcasses. This group is also confined to South America. They are generally about the size of a cat, but one species is three feet in length. Ant-eaters and Armadillos are considered, as of all the true viviparous mammalia, approaching, in the structure of their brain, most nearly to birds.

The *Tardigrada*, or Sloths, are a group of animals considerably different from the above in all respects but their want of the fore-teeth. They are herbivorous, inhabiting the forests between Mexico and Brazil, the largest not exceeding a fox in bulk. They live on trees, which they never leave, unless compelled through force or accident; and what is extraordinary, their most common posture is that of suspension from the branches, which they clasp with their arms and legs. In this attitude, they sleep, rest, and move from tree to tree. For this mode of life they are admirably adapted, their arms being twice as long as their hinder extremities; and they are by no means so slow as they are said to have been by early naturalists, who had seen them only in a state of confinement.

Fossil remains of two very large animals of this family have lately been discovered in America—the *Megatherium* and the *Megalonyx*—nearly equalling the elephant in size. From the structure of their teeth, it

has been inferred that they were leaf-eating animals, but with a short neck, unfitting them to reach the highest branches. It is difficult to ascertain the manner in which they got at their food. Professor Owen supposes, that they first cleared away the earth from the roots of a tree with their claws, and then seating themselves on

Sloth.

their hinder extremities, and grasping the trunk with their fore-feet, heaved it to and fro till they prostrated it to the ground, and then regaled themselves on its leaves.

Insectivora.

ORDER INSECTIVORA are small animals, subsisting chiefly on insects and vegetable substances. They are all nocturnal and subterranean in their habits, and most of them spend the winter in a state of sleep. From the shortness of their legs, their movements are necessarily slow. They are divided into three families—*Hedgehogs*, *Moles*, and *Shrews*.

Erinaceadæ (Hedgehogs).—These animals are called Hedgehogs because they prefer the roots of hedges as their hiding-places, and from a superficial resemblance which they bear to pigs. Their teeth shew that they are omnivorous. Nature has provided them with a bristly coat of armour, which by strong cutaneous muscles they can draw over every part of the body, or every part which is accessible, so as effectually to protect themselves from their enemies. They live on fruit and the eggs of small birds, and are torpid in winter.

Talpidæ (Moles) live chiefly under ground, feeding on insects, worms, and roots. Their feet are admirably adapted to their subterranean mode of life. From the smallness of their eyes, which are scarcely perceptible, it was long considered that the Moles were blind; but it is now ascertained that they are by no means deficient in the sense of sight. Moles have no external ears; but, from the tympanum being large, their sense of hearing is nevertheless very acute.

Sorecidæ (Shrews) are small animals, having soft hair. Some of the species are among the smallest of mammalia. The Common Shrew measures only two inches in length. The food of these animals consists of worms and insects. They burrow in the ground, seldom appearing abroad except towards night. This family is composed of *Shrews*, *Amphibious Shrews*, and *Water Shrews*.

Rodentia.

ORDER RODENTIA take their name from their gnawing habits, for which they are fitted by having the two canine teeth close together (incisors being wanting), the pairs in the several jaws working against each other. These teeth are constantly wearing away, but as constantly growing; so that when one is lost or broken, its opposite, having nothing to wear it down, becomes developed to an enormous extent. The body is heavier in the rear than in the foreparts, so that rodent animals leap rather than run.

The *Rodentia* may be divided into seven families, the technical distinctions between which are founded upon minute particulars in the structure of the cranium and of the lower jaw. 1. *Sciuridæ*, or Squirrel tribe, comprehending a large number of light and agile animals, chiefly distinguished by their long bushy tails, and by their adaptation to a residence in trees, and to live upon their produce. 2. *Muridæ*, or Rat tribe. 3. *Castoridæ*, or Beaver tribe, including the Voles, Lemmings, &c. 4. *Hystricidæ*, or Porcupine tribe. 5. *Cavidæ*, or Guinea-pig tribe. 6. *Chinchillidæ*, the Chinchilla tribe. 7. *Leporidæ*, the Hare tribe. The rodents of the fourth, fifth, and seventh families are destitute of the clavicle, which those of the first three and sixth possess.

Squirrel.

Of the family *Sciuridæ*, the *Common Squirrel* of this country may be taken as a characteristic illustration; and its form and habits are sufficiently well known to render particular description unnecessary. It lives entirely upon vegetable food, in search of which it leaps with great agility from branch to branch. In taking these leaps, when it is once thrown off by an effort of its long and powerful hind-legs, it is in a measure sustained by the horizontal spreading of its limbs and bushy tail, the hairs of which are directed laterally, so as to resemble feathers. In the *Pteromys*, or Flying-squirrel, this sustaining power is much increased by an extension of the skin of the flank between the fore and hind legs, which serves as a parachute. The *Marmots* are allied to the squirrels in the number and structure of their teeth, which are partly adapted, however, to insect food. In other respects, they are almost the reverse of squirrels, being heavy, with short limbs and a moderate-sized tail, and living on the ground, or even in burrows beneath it. They are connected with the former tribe, however, by an elegant little animal termed the *Ground-squirrel*, partaking of the habits of both: this is a native of Eastern Europe. A very remarkable kind of Marmot is one known in North America by the name of the *Prairie-dog*, or *Barking-squirrel*, on account of its voice, which resembles the bark of a small dog. It lives in great troops, in immense burrows. More allied to the squirrels in the size of their tail and active habits, but differing in their dentition, are the *Dormice*, the structure of whose teeth shews them to approximate to the next family. They chiefly subsist on vegetable food; but some species of them attack small birds. All the members of this family pass the winter in cold climates in a state of lethargy, which is most profound in the Marmots and Dormice.

The family of *Muridæ* contains the smallest, and at the same time the most prolific, of the Mammalia. No undomesticated animals are better known than *Mice* and *Rats*. The *Brown* (commonly, but erroneously, called the Norway) *Rat* made its first appearance in Paris about the middle of the eighteenth century, and in England not many years earlier. It is believed to have originally come from Persia, where it lives in extensive burrows. It is said to have arrived in Astracan by swimming across the Volga, after an earthquake, in 1727. Its astonishing fecundity, its omnivorous habits, the secrecy of its retreats, and the ingenious devices to which it has recourse, either to retain its existing place of abode, or to migrate to a more favourable situation, all conduce to keep up its almost overwhelming numbers. Where a plentiful supply of animal food is afforded them, rats will feed exclusively upon it. The Brown Rat is now speedily replacing the *Black* or *Old English Rat*, which is becoming rather a rare animal in this country, and which, from its smaller size, is an unequal match for the usurper. There is reason to believe, however, that even this is not a native of England, and that it was introduced from France about the middle of the sixteenth century. From Europe these two rats—which infest vessels equally with houses—have been sent to America, the islands of the Pacific, and many other places, in some of which they have now become a serious inconvenience. The only strictly indigenous British species of Muridæ are the *Harvest-mouse* and *Long-tailed Field-mouse*, both of them very beautiful little animals, and very interesting to the naturalist, although highly injurious to the agriculturist. A great number of species exist in various parts of the world, which do not differ widely from each other.

The *Hamsters* have teeth nearly similar to those of the rats, but their tails, instead of being long and scaly, are short and hairy, and their cheeks are hollowed into pouches, in which they can stow away a large quantity of grain for transport to their nests. They abound in the sandy plains of the north-east of Europe, from Germany to Siberia, and are very injurious, from the quantity of grain they hoard up in their extensive and intricate burrows. They have more ferocity than most of the order, and will attack any animal that comes in their way. They are believed to feed upon birds as well as upon vegetables. Allied to the rats in its dentition, and having also some points of resemblance to dormice, is the curious genus *Dipus*, or Jerboa, the general form of whose body, as well as its mode of progression, is very similar to that of the kangaroo. The enormous length of the hind-feet occasioned them to be designated Two-footed Rats by the ancients; whence their present generic name is derived.

Of the *Castoridæ*, the *Beaver* is probably the type; but this family contains many genera having a close

Beaver.

resemblance to the rats. The Beaver is distinguished from all other rodents by its horizontally flattened tail, which is of a nearly oval form, and covered with scales. The hind-feet are webbed, by means of which and the tail these animals obtain considerable swimming powers. They chiefly subsist on bark and other hard substances, and can fell trees of considerable size, of which they use the bark and twigs as food, employing the stems in the construction of their remarkable habitations. The flattened tail is employed by them as a kind of trowel, with which they plaster the walls of their houses. The Beavers are connected with the previous family by the *Arvicolæ*, or Voles, many of which bear a strong general resemblance to rats, but differ in their dentition. Most of them are partly aquatic in their habits; such is the *Common Water-rat* of this country, the food of which, like that of the Beaver, is (contrary to the general opinion) almost exclusively vegetable. To this group also belong the *Lemmings*, or Scandinavian Rats, which are remarkable for their occasional migrations in immense bodies. They are stated to advance in a straight line, regardless of rivers and mountains; and while no insurmountable obstacle impedes their progress, they devastate the country through which they pass. Most of this family lay up a winter store of food, upon which they subsist in the intervals of sleep, and they do not go abroad during that season.

The animals which are characteristic forms of the family *Hystricidæ*, are recognised at the first glance by the stiff and pointed quills with which they are armed, somewhat similar to those of the hedgehogs, but usually much larger. Besides the *Porcupines* and their allies, however, to which this description more particularly applies, this family contains several forms which connect it with the two preceding. The name porcupine is corrupted from the French *porc-épine*, a term expressive of the pig-like aspect and grunting voice of these animals, as well as of their spiny covering. They live in burrows, and have very much the habits of rabbits. The best known species inhabits the south of Italy, Sicily, and Spain. It is nearly the largest of the Rodentia, measuring almost three feet in length. There is an American genus nearly allied to the true porcupine, which has a long prehensile tail, like that of the opossums, and lives in trees.

Porcupine.

The next family, that of *Cavidæ*, contains the largest sized animals of this order, although, when compared with ordinary quadrupeds, they would be termed small. They are naturally restricted to tropical America, where they replace the hares and rabbits of cold climates. But the *Guinea-pig* is now extremely common in Europe, and is quite domesticated. The *Capybara* is an inhabitant of the sides of nearly all the great rivers of South America, and is the largest known animal of the order, being about three feet in length, and of the size of the Siamese-pig. It has a large, thick, and blunt muzzle, is destitute even of the rudiments of a tail, and is scantily covered with bristly hairs. Its semi-aquatic habits are shewn by the webbing of the feet. By this structure it can both swim and dive with much activity. Upon land

it makes but little progress, running badly, and generally diving in the water to avoid danger. It lives in small societies, and seems to be a nocturnal feeder. Another of the Cavidæ is the *Agouti*, which is an inhabitant of the Antilles and tropical America. It is about the same size as the European hare, and, like it, possesses very long hind-legs, by which it runs, or rather leaps, with considerable swiftness. In regard to its food, however, and its manner of feeding, it rather resembles the squirrel; preferring nuts to herbage, and sitting upon its haunches whilst eating. When angry, it stamps with the fore-feet, grunts like a young pig, and erects the bristly hair of the crupper in the manner of a porcupine.

The animals of the small family *Chinchillidæ* were, until recently, known only by their skins, which constitute an important article of commerce. In their general organisation, they seem intermediate between the cavies and rabbits, but differ from both of them in possessing clavicles. They are all natives of South America, chiefly inhabiting the range of the Andes, and they live socially in extensive burrows.

The *Leporidæ* constitute the last family of the Rodentia, and are distinguished from the rest by the presence of two small incisors behind the rodent teeth.

Hare.

The form and habits of the typical genus, *Lepus*, are sufficiently well known in the *Hare* and *Rabbit* of this country. A large number of species exist in the different parts of the northern hemisphere, and some are inhabitants of the arctic regions. There is one species of this country, in which the brown fur, that forms its summer coat, changes to white at the approach of winter. The hare is a ruminating animal, though without the peculiarly complex stomach of the Ruminantia. The *Lagomys*, or Rat-hare, is a very interesting genus, allied to the hare, but having nearly perfect clavicles, and the fore-legs almost as long as the hind. It is chiefly remarkable for the mode in which it lays up its store of winter provisions. It lives in solitude, or in small societies, in the mountainous parts of Siberia, and hollows out its burrow amongst stones and in the clefts of rocks, and sometimes in the holes of trees. About the middle of August, these animals collect their store of winter provender, which is formed of select herbs, and these they bring near their habitation, and spread them out to dry like hay. In September, they build up the fodder they have collected into heaps or stacks, which they place under the rocks, or in other places sheltered from the rain or snow. Where many of them have laboured together, their stacks are sometimes as high as a man, and more than eight feet in diameter. These stacks, which consist of the choicest and most succulent herbs, are often pilfered by the natives of that part of Siberia for the subsistence of their cattle and horses. A subterranean gallery leads from the burrow of the lagomys, beneath the mass of hay, so that neither frost nor snow can interrupt the animal's communication with it.

The remaining orders of Mammalia may be placed on a higher level, not merely in point of size and generally of strength, but in the character of their organisation. We are first called upon to notice a cluster of animals which are usually associated in one order, on account of their being fitted to spend the whole or most of their time in the sea, but which may be more properly divided into two. The aquatic mammalia were, till no distant date, universally regarded as fish, the external figure and medium of existence being alone looked to, and no one having observed that the animals breathe the atmosphere, suckle their young, and are in many other respects different from the finny tribes.

Cetacea.

ORDER CETACEA (Whales) are in general bulky animals, resembling fish in their external figure, and entirely fitted for living in the sea. Some are herbivorous; others, carnivorous. The head is usually of enormous comparative size, and fitted closely to the body, yet not without the seven cervical vertebræ which form an almost invariable feature of mammalian animals. The anterior extremities are fashioned into paddles, for pergressive motion; while the hind extremities are united into what appears as a tail. This so-called tail, unlike that of the fish, is disposed horizontally, thus forming a powerful oar for enabling the animal to rise from the depths of the ocean to take breath on the surface, or to dive suddenly below. Under the naked apparent skin of the whales is what is now ascertained to be the true skin, composed of a thick mesh of fibrous substance, filled out with fat or blubber; forming at once an elastic padding, to enable the animal to resist the pressure of the sea at great depths, and a comfortable wrapping, to save its natural heat from escaping into the cold element amidst which it lives. As is well known, the whales are chiefly sought for and captured for the sake of the oil produced by this peculiar coating. Another feature of the whales is the situation of the nostrils terminating at the crown of the head, and forming spiracles through which they project the sea-water, mingled with their breath.

The herbivorous Cetacea are named *Manatidæ*, from the resemblance of their anterior extremities to hands. They live upon submarine plants, and the herbage which grows on the banks of rivers. They seldom exceed fifteen feet in length. The *Dugongs* of the Indian Archipelago and Red Sea are the most remarkable species. It is supposed that the many fabulous stories regarding Mermaids have taken their rise from certain species of the Manatidæ, in which the head and face, when seen alone above the water, strongly recall the human lineaments.

The *Balænidæ* attain the length of seventy feet, of which the head always forms a large part. In the mouth, instead of teeth, is an apparatus which, in the circumstances, serves the animal more effectually for the supply of its food. This is a series of horny plates, arranged round the jaws, and forming simply a *strainer*. The animal, having taken in a huge mouthful of water, containing cuttle-fishes and other small animals, expels the water through this apparatus, leaving the prey behind, which is then swallowed. This peculiar construction has a parallel in the duck tribes, whose bills are furnished with a somewhat similar apparatus. From this *baleen*, as it is called, is derived the article in common use under the name of *whalebone*. It gives a generic name to the group of animals possessing it. The *Common Whale* (*Balæna mysticetus*) is an inhabitant of the arctic seas, and its capture, as is well known, is the subject of a great trade. The sailors transfix it with a harpoon, to which a line is attached, and when it rises exhausted to the surface, they kill it, and extract

the blubber. The great danger of this business is from the tail of the whale, which is quite able to upset a boat, or even to cut it in two. The *Rorqual* is another species, in the same seas, different chiefly in being longer, with a more slender body.

Whale Harpooning.

The *Physeteridæ* (Cachelot or Spermaceti Whales) are inhabitants of the Southern Ocean. They are distinguished by the bulk of their heads, in which a surprising quantity of fat is lodged.

The *Delphinidæ* are smaller animals, generally seen in droves, and remarkable for their active and lively movements in the water. The *Dolphin*, from which the group is named, has been the subject of many fabulous stories. It was in use for food throughout the middle ages, partly in consequence of its being allowed, as a supposed fish, to be eaten during Lent. The *Porpoises* are the most familiar on our shores, to which they often come in pursuit of herrings. One remarkable species of the Delphinidæ is the *Narwhal*, or Sea-unicorn, in which one of the front teeth is developed to the surprising length of six feet, forming, of course, a most formidable weapon. The Narwhal is, however, comparatively inoffensive.

Phocidæ.

FAMILY PHOCIDÆ comprises the remainder of the aquatic mammalia. By Cuvier they were associated with the carnaria of the land, to which, it must be owned, they make a near approach. They are, in general, much smaller animals than the Cetacea, from which they differ, too, in being fitted for a partial residence on land. Their four membraned feet form powerful oars for swimming, and can also be used in clambering along the rocks. They are covered with a short close fur, sitting flat upon the skin. They pass the greater part of their time in the water, which they only quit to bask in the sunshine and to suckle their young.

Of the two genera, the *Seals* and the *Morses*, which

Greenland Seal.

this family contains, the former presents the least departure from the general type of the order. It possesses all three kinds of teeth; but the canines are not particularly large, and the molars are neither adapted for shearing nor for grinding the food, but are furnished with angular points adapted to keep hold of and crush the slippery prey. The head of the seal resembles that of a dog, presenting the same mild and expressive physiognomy. These animals seem to possess considerable intelligence; they are easily tamed, and become much attached to their feeder. They subsist on fish, which they always devour in the water, closing the nostrils by a kind of valve. Seals of various kinds are extensively scattered over the polar regions of both hemispheres, becoming scarcer in the temperate zone. They are occasionally seen on the coast of South Britain, but are more abundant on the north of Scotland. The fur-seal of the South Seas is extremely abundant in some localities; for a period of fifty years, not less than 1,200,000 skins were annually obtained from a single island.

The *Walrus* (also called Morse, Sea-cow, Sea-horse) resembles the seal in the general form of the body and limbs, but differs considerably in the head and teeth. The lower jaw has neither incisors nor canines, and is compressed laterally to pass between two enormous canines or tusks, which issue from the upper one, and are directed downwards, sometimes attaining a length of two feet. These seem to be used by the animal in hooking up the sea-weeds on which it partly feeds. The Morse is a very bulky creature, exceeding the largest bull in size, and attaining the length of twenty feet. It is an inhabitant of all parts of the arctic seas, usually assembling in large numbers; and individuals have occasionally visited the British shores.

Two orders of the remaining Mammalia are distinguished by having the extremities serviceable only for support, and terminating in *hoofs*. They are destitute of clavicles, and may be generally described as vegetable feeders. These two orders are classed together as *Ungulata*, or Hoofed Animals. The first order we shall notice is the

Ruminantia.

The ORDER RUMINANTIA is perhaps the most natural and best determined of the mammalian class, for all the species which compose it seem constructed, as it were, upon the same model, the camels alone presenting any considerable exceptions to the general characters of the group. The first of these characters is the entire absence of incisor teeth from the upper jaw; whilst the lower appears to possess eight: of these, however, the two outer ones are really canines, which have taken the form of incisors, so that the number of the true incisors is six, as in the other viviparous mammalia. The molars are almost always six in number, both above and below, and have their crowns marked with two double crescentic ridges of enamel, which aid in masticating the food. The feet are each terminated by two toes and two hoofs, which present a flat surface to each other, appearing as though a single hoof had been cleft; hence the names that have been applied to these animals of cloven-footed, &c. Behind the hoof there are always two small spurs, which are the vestiges of lateral toes.

The name of the order intimates the singular faculty possessed by these animals of masticating their food a second time, or 'chewing the cud.' This faculty depends on the structure of their stomachs, which are four in number. The food, which is cropped by the incisor teeth, is swallowed almost without mastication, and is moistened in the stomach; and after being compressed into little pellets or *cuds*, is returned to the mouth, to

be rechewed while the animal is at rest. When this operation has been performed, the food is transmitted to the true digestive stomach. This remarkable provision has a very interesting adaptation to the general structure and characters of these animals. The Ruminantia, taken as a group, are timid, and destitute of powerful means of defence against their foes. They rather seek their safety in flight when attacked. Their food, consisting chiefly of the grasses of various kinds, requires to be thoroughly masticated before it can be properly digested. When feeding, they are liable to many alarms; and if they were compelled to spend a considerable time in masticating their food before swallowing it, they would often be in danger of starvation, by being obliged to leave the pasture before their wants were supplied. But by their power of subsequent rumination, they are enabled to dispense almost entirely with the first mastication, and to feed with comparative quickness. They convey a store of food into the first stomach or paunch; and then, retiring to a secure place, they prepare it for digestion at their leisure.

The whole structure of these animals corresponds with the account just given of their habits. Their legs are long in proportion to the body, and the spinal column is very flexible; both which conditions are favourable to great activity of motion. They are endowed with a very acute sense of smell, which seems to be the guide in the selection of food. Their ears are placed far back, and are very movable; and these are well adapted to catch sounds from behind, so as to warn the animals of danger whilst feeding. The eyes are placed at the sides of the head, and the pupil is in the form of a horizontal oblong; so that the range of vision along the surface of the earth is very great, and the animals can easily look behind them when pursued. Their means of defence consist in the use of their horns to gore an enemy, and of their hind-feet to kick; but it is only when peculiarly courageous, or in defence of their young, that single animals of this order will act on the offensive, or stand on the defensive, against others of proportional size and strength.

The Ruminants are, of all animals, the most useful to man. They supply him with a large proportion of his animal food. Some serve him as beasts of burden; others furnish him with their milk, their tallow, hair, leather, horns, and other useful products.

The great resemblance which exists among the very numerous members of this order, renders the distribution of them into families, each characterised by some important peculiarity, a matter of some difficulty. These subdivisions are, probably, best formed from the character of the horns, which are possessed by the males of all the species in their natural state, excepting such as (like the camel) connect this order with other groups. The horns are essentially bony prominences from the forepart of the skull. In some Ruminants, commonly termed *cattle*—such as oxen, sheep, goats, and antelopes—these prominences are covered with an elastic sheath, formed as it were of agglutinated hair, which continues to increase by layers during life. It is to the substance of this sheath that the name of *horn* is commonly applied, whilst the bony support is termed the *core;* this grows during life, and never falls. In the *Giraffe*, again, the bony prominences are covered with a hairy skin, which is continuous with that of the head; and here, too, the bony part of the horn is permanent. But in the *Deer*, these prominences, which are covered for a while with a hairy skin (commonly termed *the velvet*), like the other parts of the head, have at their base a ring of bony tubercles, which periodically enlarge, and compress the nutritive vessels of the horns. These accordingly die, and fall from the skull; and the animal remains defenceless. Others, however, are reproduced, generally larger than before, which are destined to undergo the same fate. These horns, periodically renewed, are usually styled *antlers*.

The Ruminants with horny sheaths to the bony prominences, may be divided into three families:—*Antelopidæ*, or Antelope tribe, characterised by the lightness of their forms and the activity of their movements, and by the solidity of the bony core;—*Capridæ*, or Goat tribe: in these the bony core is partly occupied with cells, and the general form approaches that of the Ox tribe, but the horns are directed upwards and backwards;—*Bovidæ*, or Ox tribe: these have the horns directed upwards and forwards; the form is robust, and the movements heavy. The division of the Ruminants in which the horns are periodically cast off, constitutes only one family—that of *Cervidæ*, the Stag tribe. Another family, including only the Giraffes, and named *Camelopardæ*, is characterised by the shortness and permanence of the horns, which are covered with a skin. Of the Ruminants without horns, there are two distinct families—the *Moschidæ*, or Musk Deer, which are remarkable for their elegance and lightness, and differ but little from the rest of the order, save in the absence of horns; and the *Camelidæ*, or Camel tribe, which, in their dentition and in the structure of the extremities, exhibit a transition to the Pachydermata.

The family *Antelopidæ*, remarkable for the slenderness of form and swiftness of foot of the animals composing it, contains above seventy well-ascertained species, bearing a strong general resemblance to each other. Most of these are natives of Africa; a few species, however, inhabit Asia; a still smaller number exist in America; and one only, the *Chamois*, now remains in Europe. Among these numerous species, we meet with

Chamois.

forms that remind us of the other families of the Ruminantia—the Ox, Goat, Stag, &c. They generally associate in large herds, which migrate together in search of pastures. A species well known to the colonists of South Africa is the *Spring-bok;* which occasionally visits their cultivated lands, during seasons of drought, in innumerable herds, causing devastation wherever they pass. Another noted species is the *Gazelle*, celebrated for its beautiful eyes, as indicated by the poet:

> I never nursed a young gazelle,
> To glad me with its soft black eye, &c.

They are extremely vigilant and timid; and the speed of the swiftest species surpasses that of every other mammiferous animal. Those which are adapted to live on rocks and mountains exhibit the most remarkable agility, and fearlessness of those dangers which their habits would seem to involve: they walk with perfect composure along the giddy brinks of the most awful precipices, climb and descend with wonderful care and precision, and leap up or down to the smallest surface that will contain their collected feet, with perfect firmness; and yet they are so fearful of any supposed enemy, that it is difficult to get within gunshot of them. Allied to the Antelopes is a very curious genus, the *Gnu*, which at first sight seems to be a monstrous being, compounded of parts of different animals. The body and crupper,

also the tail, neck, and mane, resemble those of a horse; whilst its horns are like those of the Cape buffalo; and

Gnu.

its legs are as slender and light as those of a stag. It inhabits Southern Africa.

The family of *Capridæ* is connected with the last by many antelopes which, like the chamois, approach the goats in form. It includes only the *Goats* and *Sheep*. The original stock of the domestic breeds of the former appears to be indigenous to Persia, where it inhabits the mountains in large troops. The goats of Angora, Tibet, &c., celebrated for the fine quality of their hair, are no more than varieties of the common species. The *Ibex*, which inhabits the mountains of the Old World, and especially the Caucasian chain, is distinguished by the size and strength of its horns. It is said that this animal fearlessly precipitates itself down precipices, always falling on its horns, the elasticity of which secures it from injury. The *Sheep* appear to have extremely little real difference from the goats; a large number of races exist, the relation of which to each other is uncertain; and there is doubt as to the original stock of the whole. Of the domestication of this animal, we have an earlier record than of any other; and on its use to man, there is no need to enlarge in this place.

The species of the family *Bovidæ*, or Ox tribe, are comparatively few. They are all large animals, with a broad muzzle, heavy and massive body, and stout limbs. Of the original stock of the domestic ox, we have no certainty, since, as in the case of horses, the existing races of wild cattle may have all been descended from those which have been at some period subservient to

Bull.

man. Of all the animals which have been reduced to his service, the ox is, without exception, that to which he is most indebted, for the extent and variety of his means of usefulness. The universal utility of the animal appears to have been very soon detected; and we find, consequently, that its domestication soon followed that of the sheep, and that it is mentioned in the most ancient records as a servant of man, long before either the horse or dog is noticed. The ancient accounts of the *Urus*, or Wild Ox, declare it to have been an animal of great size and fierceness, with large spreading horns; and bones are found in the most recent deposits, both in this country and on the continent, which correspond with that description. Many races or breeds of oxen exist in different parts of the world, which were probably all descendants from one stock, and yet differ considerably from one another. Most of those inhabiting the torrid zone have a lump of fat upon the shoulders, which increases in size in proportion to the abundance of their food. This is especially remarkable in the *Indian* or *Brahmin Bull*, which, being held sacred by the Hindoos, is supplied with food in great profusion, and leads an indolent life. When left to themselves, their form changes; they become less bulky and more active, and the hump, in particular, greatly diminishes. Some of the tropical races of oxen are no larger than a hog.

Amongst the undomesticated species of this family, which have all a strong general resemblance to each other, and are the most powerful and savage animals of the whole order, may be noticed the European *Bison*, which was formerly spread over Europe, but is now restricted to Lithuania and the Caucasian region; the American bison, commonly called *Buffalo*, which inhabits

Bison.

all the temperate parts of North America; the *Indian Buffalo*, of which there are several different races (in one the horns include a space of ten feet from tip to tip), some having been domesticated; the *Cape Buffalo*, an extremely ferocious animal, with large horns, first directed downwards so as nearly to cover the forehead, inhabiting the woods of Caffraria; and the *Musk Ox*, a species inhabiting the coldest regions of North America, with short legs, and long hair reaching the ground, which diffuses more strongly than the rest the musky odour common to the whole genus, and which is particularly noticeable in the European bison.

The family *Cervidæ*, or Stag tribe, includes, like that of antelopes, a large number of species differing but little amongst each other, very widely diffused over the earth's surface, and easily separated from others by the character of the horns. With the exception of the reindeer, however, the female is destitute of horns, save in a few rare individual cases, analogous to those amongst birds in which the hen assumes the plumage of the cock-bird. This never takes place until the latter part of the animal's life. The substance of the horns, when completely developed, is that of dense bone, without pores or internal cavity; their figure varies greatly according to the species, and even in the same individual at different ages. These animals are extremely fleet, and live mostly in forests, where they feed on grass, the leaves and buds of trees, &c.

This very extensive genus may be subdivided into sections, according to the form of the antlers. In some species they are wholly or partially flattened. This is the case, for example, with the *Elk*, one of the largest

existing species, which lives in troops in the marshy northern forests of both continents. In size it approaches the horse, and sometimes exceeds it. The antlers of the male, at first dagger-shaped, and then divided into narrow slips, assume, at the age of five years, the form of a triangular blade, with tooth-like projections on the outer edge. These increase with age; so that the horns have at last fourteen branches proceeding from each expanded portion, and weigh fifty or sixty pounds. To this group also belongs the *Reindeer*, so serviceable to the Laplanders, which is the only species properly domesticated,

Reindeer.

though others are doubtless susceptible of being so. The *Fallow-deer*, now naturalised in this country, but probably introduced from the south of Europe, or even originally a native of Barbary or Western Asia, is another species of this group. The remains of a gigantic species of deer, belonging to the same section, are frequently found in peat-bogs, and other recent deposits in this country, and more especially in Ireland, whence the name *Irish Elk* has been given it. Judging from specimens of which the greater part of the bones have been discovered, it must have stood more than six feet high, and have been nine feet long; but there is no doubt, from the dimensions of many of the horns which are preserved (one pair measuring thirteen feet between the tips), that this is under the average size of the race.

The species with round antlers are more numerous; those of temperate climates change colour, more or less, with the seasons. The Common Stag, or *Red Deer*, is the best known of these, being indigenous to the forests of all Europe and of the temperate parts of Asia. The Canadian Stag, or *Wapiti*, the Elk of the Anglo-Americans, is a fourth larger. There is also another species, inhabiting Virginia and the central parts of North America, which is smaller than the European stag, and is known as the *Deer*. A large number of species are indigenous to Central and Southern Asia, of which some have been naturalised elsewhere.

Of the family *Cameloparda*, only one species was for a long time known to exist; but there are probably two, or even three kinds of giraffe, all of which are natives of Africa, mostly frequenting the borders of the deserts. Its remarkable form, depending chiefly on the great length of the neck and fore-legs, is familiar to every one. In general structure, however, it closely resembles the deer, differing from them in the permanence of the horns. It has also some points of affinity to the camels, especially in the length of its neck, the existence of callosities, or hard surfaces, on the breast and knees, and the absence of the small spurious hoofs. It is the tallest of all animals, the head being frequently raised eighteen feet from the ground. Its disposition is gentle, and it feeds on leaves; browsing upon the young branches at a height much above that which any other animal can reach, and drawing them towards its mouth by its prehensile tongue. It lives in small troops of five or six individuals, and is very timid, although capable of powerfully defending itself by kicking. Notwithstanding its length of neck, the number of vertebræ

Giraffe.

which this part contains is no greater than in other Mammalia.

The *Moschidæ*, or Musk Deer, are completely intermediate between the true Deer and the Camel tribe, which last connects the Ruminantia with the Pachydermata. They resemble the ordinary Ruminants in the lightness and elegance of their forms, and in the nimbleness of their movements; and differ chiefly in the absence of horns, and in the projection of the canine tooth on each side of the upper jaw, as in the camels. The name of this group has been derived from the common *Musk*, the males of which secrete the odoriferous substance so called in a small glandular bag. This species is nearly destitute of the tail; and the hairs, which completely cover it, are so coarse and brittle, that they might almost be called spines. It is confined to the mountainous region between Siberia, China, and Tibet, from which most of the Asiatic rivers descend. Its habits are nocturnal and solitary, and its timidity extreme. The other deer inhabit the warmer parts of Asia and the Eastern Archipelago; they have no musk-pouch. They are the smallest and most elegant of the Ruminantia, and are active and gentle in their habits.

The *Camelidæ*, or Camel tribe, approximate to the succeeding order, and especially to the whole-hoofed division constituting the Horse tribe, more closely than any other Ruminants—to such a degree, indeed, that some naturalists prefer associating them with that group. They have always canines in both jaws, and two of the incisors have also the same pointed shape. The animals of this family are much less elegant in form and graceful in action than the other Ruminants; but their organisation is, equally with theirs, perfectly adapted to the circumstances in which they exist. The family contains two groups—the *Camels* and *Llamas;* the former are restricted to the Old World, and the latter correspond to them in the New.

In the true *Camels*, the two toes are united below by a kind of horny sole, almost to their points, which terminate in small hoofs; and there is a soft cushion beneath the foot, by which it bears upon the sandy surface over which it is formed to move. Two species are known—one called the *Bactrian*, or Two-humped Camel, and the other the *Arabian*, or One-humped. Both are completely domesticated, and their utility as beasts of burden is universally known. The first species is employed chiefly in Central Asia, the latter in Arabia, North Africa, Syria, Persia, &c. The Two-humped Camel is the larger and stronger, being capable of sustaining a burden of above 1000 pounds, and is best adapted for rugged ground. The other is the most abstemious, and the best fitted for the sandy desert.

The *Dromedary* is merely a lighter variety of it, possessed of greater fleetness and power of endurance.

Bactrian Camel.

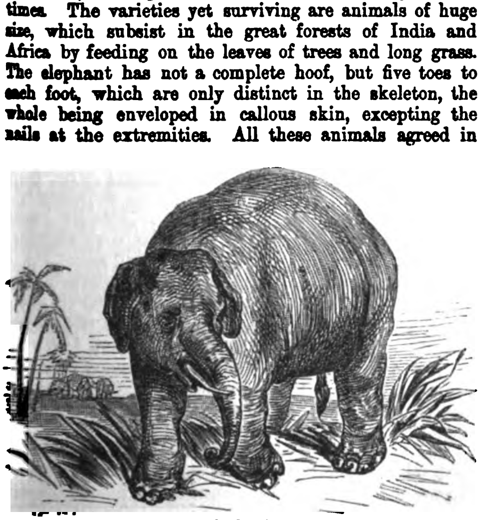
The flesh and milk of the camel serve as food, and the hair for the manufacture of cloth. Their humps, principally composed of fat, are provisions of superabundant nutriment, which are gradually absorbed and disappear on the occasion of a scarcity of other food, as is observed at the end of a long journey. By resting on their callosities, they are enabled to repose on a scorching surface, and their stomachs are adapted to contain a supply of water sufficient for several days.

The *Llamas* of South America are much smaller than the camels; they have the two toes quite separate, and are without humps. They were the only beasts of burden possessed by the Peruvians at the time of the conquest. They can only make short journeys, and the largest of the four species known cannot sustain more than 150 pounds. Remains of a fossil species have been found, which must have equalled the camel in stature.

Pachydermata.

The second of the Ungulated orders is the PACHYDERMATA, so called from the thick skin with which most of them are invested. The animals of this order do not ruminate. They may be divided into three sections or groups.

Of the first group, *Proboscidea*, the *Elephant* is the only living genus; other species, as the *Mammoth* and *Mastodon*, having become extinct in not very remote times. The varieties yet surviving are animals of huge size, which subsist in the great forests of India and Africa by feeding on the leaves of trees and long grass. The elephant has not a complete hoof, but five toes to each foot, which are only distinct in the skeleton, the whole being enveloped in callous skin, excepting the nails at the extremities. All these animals agreed in



Elephant.

possessing a pair of enormous tusks or front teeth, and a very elongated nose or proboscis; and it is probable that this last organ was formed, as in the elephant, to answer the purposes of a hand—laying hold of large objects by coiling itself round them, and of small by means of the finger-like organ at its extremity. The magnitude of the sockets necessary to hold the tusks, renders the upper jaw so high, that the nostrils, which are prolonged through the trunk, are placed in the skeleton near the top of the face. The trunk is admirably adapted to serve both as a means of laying hold of food and imbibing water: when the capacious nostrils are charged, the animal bends the trunk towards the mouth and discharges the liquid into its throat. By this organ, the shortness of the neck—rendered necessary by the weight of the head—is fully compensated. The cavity for the brain by no means corresponds with the external form of the skull; for in order, as it would seem, to give a larger surface for the attachment of the muscles of the trunk, the outer layer of bone is widely separated from the inner, and between the two are a number of large bony cells.

In none of the Proboscidea has the lower jaw of the adult any front teeth. The arrangement of the grinders differs in the various species; but in all they are composed of alternating plates of hard *enamel* and softer *bony* matter, cemented together by a third substance, which is termed the *cortical*. These grinders are in constant progress of renewal; but they succeed each other, not by rising from below upwards, as in man, but by being pushed forwards from behind, in proportion as the tooth before each is worn away. The tusks are only changed once; but, like the cutting-teeth of the rodents, they are constantly being renewed at the roots. Two species of elephants exist at the present day, both of which inhabit tropical climates—one in Asia, the other in Africa. Remains of the mammoth are found chiefly in the north of America and in Siberia; and from a nearly perfect specimen, which was discovered frozen in the ice near the mouth of the river Lena, it appears that this species was adapted to live in cold climates—the skin being densely covered with hair of two kinds. The tusks of the elephant serve not only as weapons of offence and defence, but to root up small trees and tear down cross-branches, either to obtain their leaves or to make a passage for the bulky body of the animal through the tangled forest.

Of the second group, sometimes called the *True Pachydermata*, the first family is that of *Suidæ*, the Pig kind. It is characterised by the peculiar thickness of the skin, and by the presence of four toes on each foot. They have three sorts of teeth in each jaw; the canines are usually long, and project forward as tusks; the anterior molars are more or less narrow and conical, whilst the posterior are tuberculated. The food is principally vegetable, but admits of considerable variation. The domesticated pig is well known to be quite an omnivorous animal. In the true *Pigs*, the foot has two toes furnished with large hoofs, and two much shorter ones that scarcely touch the ground. The *Wild-boar*, which abounds in some parts of the continent of Europe, is well known to be a very ferocious animal; and the domesticated race which is derived from it often exhibits indications of the same character. One of the most curious animals of this tribe is the *Babyroussa*, a native of the Indian Archipelago; the upper canines of which are very long, and grow spirally upwards and backwards. These serve as defensive weapons of a very powerful description, inflicting severe lacerations by an upward stroke of the head. The *Peccaries* of South America want the external toe, and the central ones are partly joined together, as in the Ruminants; to which the complex structure of their stomachs also exhibits their affinity.

With the family of Suidæ is probably to be placed the *Hippopotamus*, or River-horse, which seems in many respects intermediate between the pig and the elephant; whilst by its aquatic habits, and the conformation by

which it is adapted to these, it approximates to the Dugongs. Only one species is known, which is now

Hippopotamus.

confined to the rivers of Central and South Africa. But for its short, thick, and very blunt muzzle, it might be compared to a gigantic pig. The canine teeth are long; the upper ones straight, and the lower curved backwards, so that they rub against each other. Although courageous when attacked, these unwieldy inhabitants of the waters are in their nature shy, and feed entirely on roots and other vegetables, seeming to prefer those which are partially decomposed by the action of water.

The second family of true Pachydermata—to which the name of *Tapiridæ*, or the Tapir tribe, may be given—resembles the first in the thickness of its skin, but differs in the arrangement of the toes, of which there are only three on each hind-foot, and sometimes also in front, without any central cleft. There is considerable variation in regard to the teeth; but the whole family is exclusively herbivorous. No members of it exist in Europe at the present time; but fossil remains of very large species are abundant in some localities. The *Tapir* of America is about the size of a small ass, with a brown and almost naked skin, a short tail, and fleshy neck that forms a crest at the nape. It is common in humid places and along the rivers, and its flesh is eaten. The nose assumes the form of a short fleshy trunk—the rudiment, as it were, of that of the elephant. Other species have been recently discovered of a larger size; one of which has the bones of the nose still more elongated, approaching a very remarkable fossil genus—the *Palæotherium*. This seems to have been an animal nearly allied to the Tapirs. Remains of several species, varying in size from a rhinoceros to a small sheep, have been found in the gypsum quarries of Paris, the fresh-water deposits of the Isle of Wight, and other places.

To this family belongs the *Rhinoceros*, which is remarkable for its large size, and for the kind of horn, composed of a solid fibrous substance, resembling agglutinated hairs, which is supported on an arch formed by the nasal bones. Several species exist in different parts of the tropical portion of the Old World. They are naturally stupid and ferocious, frequenting marshy places, and subsisting on herbage and the branches of trees. In some species a second horn exists behind the first. The upper lip is generally elongated, and has some power of prehension. The bones of the rhinoceros have been disinterred in many parts of Europe. There is a curious little animal, the *Hyrax*, which is about the size of a rabbit, and was formerly placed among the Rodentia; it is, however, little else than a rhinoceros in miniature, without the horn. It is not uncommon in rocky places in Africa and Syria, and one species ascends trees. It is probably the animal spoken of in Proverbs xxx. 26, as the *cony*.

The third group of Pachydermata, the *Solidungulata*, contains only one family—that of the *Equidæ*, or Horse tribe. Though there is only one apparent toe and single hoof to each foot, there are appendages beneath the skin which represent two lateral toes. The well-known animals of this tribe, the Horse, Ass, Zebra, Quagga,

Zebra.

Onagga, and Dzegguetai, are commonly regarded as belonging to but one genus; but the first of these is probably to be separated from the rest, from the circumstance of its tail being wholly clothed with long hair, whilst that of the rest has long hair only towards the tip. The Ass and Horse are noted for their usefulness to man as beasts of burden, docility and strength being in them combined in a remarkable manner, but particularly in the horse. In a wild state, the horse lives in great herds, browsing on grassy plains, and occasionally moving over them with marvellous swiftness.

All the animals just named agree in their dentition. There are six incisors to each jaw, which, during youth, have their crowns furrowed by a groove, and six molars on each side, above and below, with square crowns, marked, by plates of enamel which penetrate them, with four crescents. The males have, in addition, two small canines in their upper jaw, and sometimes in both; these are always wanting in the females. Between the canines and the first molar there is a wide space, which corresponds with the angle of the lips, where the *bit* is placed, by which alone man has been enabled to subdue these powerful quadrupeds. None of the species of this family are indigenous to America.

Carnivora.

The animals composing the ORDER CARNIVORA are separated from the other Mammalia possessing distinct fingers, by the presence of three kinds of teeth, and from these orders they are distinguished by characters which point them out as especially formed for the pursuit and destruction of large animals. They possess in the upper and lower jaw six incisor teeth; a large, strong, and pointed canine tooth on each side; and molar teeth which are evidently formed for cutting and tearing, rather than for bruising or grinding. The form of these teeth varies, however, in the different genera, in accordance with their several habits. These molars consist of three kinds: the anterior, immediately following the canines, which are always more or less pointed, and are termed *false molars;* the next class, formed especially for cutting the flesh upon which the animals feed, are termed *carnivorous teeth;* and the posterior are tuberculated, with flattened summits.

The proportion which these different classes bear to each other in number and development, accords with the degree of the carnivorous propensity of the animal, and furnishes important characters in the subdivision of the order. The more the surface of the molar teeth is raised into points and edges, and the more the action of the jaws is restricted to the scissor-like movement by

which these edges are made to meet and pass each other, the more purely carnivorous is the regimen of the animal: this is well seen in the Cat tribe. On the other hand, the more the molar surfaces are flattened, and the greater the lateral grinding motion of which the jaws are susceptible, the greater is the probable admixture of vegetable food: this is seen in the Bears. The general structure of the body, and especially that of the extremities, is modified in a corresponding manner, in accordance with the habits and propensities of the animal. In all, the toes are furnished with claws, which are peculiarly sharp in the Cats, and are in them kept ready for use within a sheath, from which they can be projected at the will of the animal. The stomach of the Carnivora is very simple in its form, and the intestines are short, in accordance with the easily digested character of their food.

The whole bony and muscular system exhibits a similar modification. Thus, whilst the powerful yet active and flexible movements of the purely carnivorous animals are adapted only to the pursuit and destruction of living prey, the more sluggish habits of most of the Bear tribe, their peculiar mode of progression, and the modified structure of the skull, the teeth, and the limbs, are all equally applicable to the mixed nature of their food. The difference in the conformation of the extremities, and in the mode of using them, is very striking in these two antagonised groups. In the former, the ends of the toes only touch the ground, the heel being considerably raised into the air; in this way, the limbs can be used to much greater advantage in running and springing: the animals possessing this conformation are termed *Digitigrade Carnivora*. In the latter, the whole foot rests on the ground—a structure more favourable to the maintenance of a firm position, but preventing great activity of progression: these are called *Plantigrade Carnivora*. In the seals, which may be considered as Carnivora fitted for a sea-life, there is a third very remarkable variety of conformation in the extremities. Here, as we have seen, the anterior, as well as the posterior feet, are formed for swimming, being spread into fin-like paddles; and the whole arrangement of their organs is admirably adapted to the pursuit and capture of their scaly prey.

The *Carnivora* may be subdivided into four families, each containing a well-known form. 1. *Felidæ*, or Cat tribe.—In these the destructive power is most highly developed. They are characterised by their short powerful jaws, their retractile claws, and the peculiar adaptation of their teeth for cutting. They have but one small flattened molar tooth above, and no corresponding one below. 2. *Canidæ*, or Dog tribe.—These, like the cats, are digitigrade; but their claws are not retractile; and they have two flat tuberculated molars behind the great flesh-cutter. 3. *Mustelidæ*, or Weasel tribe.—These are mostly semi-plantigrade, a portion of the sole touching the ground. They are distinguished by their long narrow bodies, and by the presence of only one tuberculated molar. 4. *Ursidæ*, or Bear tribe.—These are the only true Plantigrade Carnivora. Most of them possess several tuberculous teeth. In some systems, the *Phocidæ*, or Seals, are presented as a fifth family of Carnivora.

The *Cat* tribe includes a large number of animals very closely resembling each other in structure and aspect—so closely indeed, that many of the species can only be distinguished by their size, and by the markings of their skin. They all agree, too, in the mode of catching their prey, which is to steal upon it unawares, and seize it with a sudden spring, in which they expend their energy, often slinking off when once baffled. It is very difficult to subdivide the family, on account of the strong general resemblance of its members. Most of them are sufficiently well known to render any peculiar description necessary. It may, however, be remarked, that some species are found in almost all tropical and temperate countries, and that those of different parts of the globe *represent* each other in a remarkable manner. Thus, the *Lion* and *Tiger* are inhabitants of Africa and

Tiger.

tropical Asia; in America, they are replaced by the *Puma* and *Jaguar*, which are confined to that continent. In the same manner, we find the *Panther* and *Leopard* spread over tropical Asia and Africa; the *Ounce*, inhabiting the Asiatic mountains; the *Caracal*, in Turkey and Persia; and the *Lynx*, in Northern Europe. These are represented by the *Ocelot* in South America, the *Lynx* of Canada (differing from the European), and other less-known species. The Felidæ, like the noble falcons, will only eat the flesh of animals they have themselves killed, except when in a state of domestication or confinement, or when compelled by hunger.

The family of *Canidæ* includes a much larger number of different forms, some of which approximate to the Cat tribe, and others to the weasels and bears. This tendency to variation from a typical form is most remarkably shewn in the races of the *Common Dog*, which are believed to have all had the same origin, although the commencement of most of them is entirely unknown. The animals of this family agree in their greater or less adaptation to a mixed diet. Although animal flesh naturally constitutes the principal food of all, they do not attack living animals with a degree of boldness proportional to their strength; and many of them feed upon carrion, sometimes even when it is much putrefied. The *Wolves*, *Foxes*, and *Jackals*, are the animals which most nearly approach the dog; and the first of these is regarded by many naturalists as being really identical. A very curious connecting-link between this division of the family and the hyænas, is the Wild Dog of the Cape (*Lycaon picta*). This resembles the dog rather than the hyæna in its teeth; but in its tall gaunt form, and general aspect, it is more analogous to the latter, which it is also believed to resemble in internal formation. It lives in numerous packs, which often approach Cape Town and devastate the environs.

The *Hyænas* constitute a group remarkably distinct from the true Canidæ, and yet bearing enough of their characters to require to be associated with them. They are more purely carnivorous than the dog tribe, and in the deficiency of tuberculated molars, approach the cats. But they differ from these, not only in general aspect, which is much more nearly allied to that of the dog, but also in the absence of the retractile power of the claws, and in their propensity to feed on carrion. The teeth are peculiarly adapted for crushing bones, and their jaws are shorter than those of the dog, but longer than those of the Felidæ. In many other points of structure, the Hyænas are intermediate between the two groups. They are peculiarly ferocious animals, combining the persevering *doggedness* of the one tribe with the furious blood-thirstiness of the other. Their habits are nocturnal—more so than those of most other

Carnivora. Hyænas are now chiefly confined to Africa and the south of Asia; but there is no doubt, from the

Hyæna.

abundant remains of them which are preserved to us, they must have formerly lived in large numbers in this country and in other parts of Europe.

Another curious South African animal conducts us from the hyænas towards the *Civet* tribe, which consists of small animals, some resembling the cat in form, but having two or more tuberculous grinders, and in many instances a plantigrade walk. In the true *Civets*, there is a pouch situated near the tail, containing a secretion of a musky odour, which is valued as a perfume. They are beautiful spotted animals, natives of Africa and India; they are of an indolent disposition, easily tamed, and feed partly on fruits. Allied to these is the celebrated *Ichneumon* of Egypt, which is an animal larger than our cat, and as slender as a marten, sharing in the highly carnivorous propensities of the next family. It chiefly hunts for the eggs of crocodiles, by destroying which it prevents the excessive multiplication of those reptiles. It is easily domesticated, and exhibits much intelligence; and it is brought up in houses, to keep them free from mice and other small animals. The ancient allegation of its entering the throat of the crocodile to destroy it, is quite fabulous. The common Indian species is celebrated for its combats with the most venomous serpents.

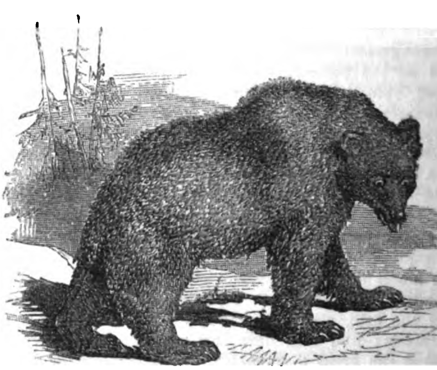
The *Mustelidæ* are the most *blood-thirsty* of all the Carnivora; but they are not so well adapted for devouring flesh as the Felidæ. These animals, on account of their length of body and the shortness of the limbs, which permit them to pass through very small openings, may be described as *Vermiform*. All the members of this family are semi-plantigrade; and they thus conduct us to the truly Plantigrade Carnivora. The *Weasel* of this country is a very characteristic example of the family; it is one of the most sanguinary of all, but confines itself chiefly to small animals, destroying large numbers of mice, rats, moles, &c. The *Ferret* and *Marten*, which are allied species, are bolder, having been known to attack man; and the *Polecat* is a great enemy to the farmyard, game-preserve, and warren. All these animals have a strong and disagreeably odorous exudation from a pouch under the tail; but it is most disgusting in the last, from which cause it is often called the *Foumart* (a corruption of *foul marten*). The *Skunks* are an American tribe, intermediate between the weasels and badgers, and are remarkable for the intensity of their nauseous suffocating stench.

The *Otters* constitute an aquatic form of this family, having the same general aspect and dentition as the weasels, but being readily distinguished from all other genera of the family by their webbed toes and horizontally flattened tail. They subsist on fish. Several species exist, which are diffused pretty universally over the globe, with the exception of Australia, where they are replaced by the extraordinary *Ornithorhynchus* (see page 174). The Indian species is employed for fishing, as the dog for hunting. A large species frequents the waters of the North Pacific Ocean, along the shores of Kamtchatka and Siberia, where it is hunted for its blackish velvet-looking fur. This species is said to feed partly on sea-weed. The *British Otter* also occasionally

Otter.

visits the sea, swimming to some distance from the mouths of the rivers which it has descended. It is said to burrow in their banks; but this is not correct, as it lives only in natural excavations. When the supply of fish is scanty, it has been known to resort far inland, and to attack lambs, sucking-pigs, and poultry.

The true Plantigrade Carnivora, constituting the family of *Ursidæ*, participate in the comparative slow motion and nocturnal life of the Insectivora; and like them, too, the species which inhabit cold countries pass the winter in a dormant state. In the *Bears*, the



Brown Bear.

cartilage of the nose is elongated and movable, somewhat resembling that of the shrews. These animals possess a great facility, from the structure of the sole, for rearing themselves up on their hind-feet; and this may be especially noticed in such as are, like the bears, fruit-eaters, becoming carnivorous only from necessity; they are thus enabled to climb trees in search of food. The bear also digs the ground in search of earthworms, on which it feeds, besides slugs, snails, small mammalia, and birds, eggs, and vegetables.

The *Badgers* (*Taxels* or Badgers of America) and the *Wolverines* form a tribe connecting the Bears with the Mustelidæ. The *Badger*, for example, is only semi-plantigrade, and has a dentition very like that of the weasels and otters, but adapted for a less carnivorous regimen. But it has the tardy gait and nocturnal habits of the other plantigrades; it does not, however, become torpid in winter. All these animals, like the weasel tribe, have the power of emitting a fetid odour

at will. The European and American badgers burrow with great facility, by means of the long claws of their fore-feet. They go forth in search of food only by night; and devour small animals which fall in their way, and such vegetable substances as roots, earth-nuts, and beechmast, almost indifferently. They are endowed with astonishing strength of jaws, and great muscular force, so as to confer upon them considerable powers of resistance. Of the Wolverines, the most celebrated species is the *Glutton* of the north, which is about the size of a badger: it is reputed to be very sanguinary and ferocious, subduing the largest animals by leaping on them from a tree. Some species of this tribe approach very closely to the Mustelidæ.

Cheiroptera.

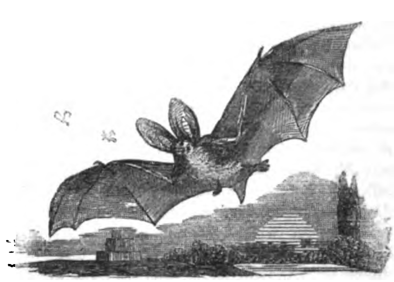
The ORDER CHEIROPTERA (*Bats*) have been placed thus high in the Animal Kingdom, in consideration of several peculiarities shewing an affinity between them and the Monkeys. They are generally small animals, of insectivorous habits, and their distinguishing peculiarity is a membrane extending over the very elongated fingers of the fore-arm, enabling them to rise and pursue their way in the air, in quest of their insect prey. The four fingers, forming the framework of the wing, correspond with those of the human hand, though much prolonged; and there is also a small thumb, terminating in a hook-like nail, which serves the animal for climbing on precipices, and in making its way along the ground. The toes of the hind-feet are short, and furnished with claws, by which the bats suspend themselves from the trees or walls on which they rest, hanging with the head downwards. From some peculiar sensitiveness of wing, the bat can make its way, while deprived of eyesight, and even of hearing, among a confused variety of objects, without ever coming in contact with any. In many of the insectivorous bats, the organ of smell is furnished with curious leaf-like appendages, formed of the integument, doubled, folded, and cut into curious and most grotesque forms. The group in which these are most remarkable, is one which avoids the light of day more than others. The arrangement may be considered as an unusual development of the sense, specially useful in those circumstances.

The families composing the *Cheiroptera* are arranged in two divisions—one of them including the strictly Insectivorous Bats, the other comprising those which are Omnivorous, or feed chiefly on fruits. In the former, the molar teeth have tubercles, like those of the Insectivora, and the intestine is short; in the latter, the molar teeth have flattened crowns, and the stomach is complex. The Insectivorous group comprises four families:—1. *Rhinolophinæ;* in these, the nose-leaf is of complicated structure, and is membranaceous; the index or fore finger has but one joint; the wings are large and broad. 2. *Phyllostominæ*, which have the nasal appendage simple and fleshy, and an index-finger of two joints. 3. *Vespertilionidæ*, which are destitute of nasal appendages, and have a single joint in the forefinger. 4. *Noctilionidæ*, which are also destitute of nasal appendages, but have two joints in the index-finger.

To the first of these families, the *Rhinolophinæ*, belong the greater and lesser *Horse-shoe Bats*, which are found in the darkest and most secluded retreats of our own country; their name is derived from the peculiar form of the anterior nasal appendage. The family contains many other genera and species, most of which are inhabitants of the Old World. One of the most curious is the *Nycteris*, which has the power of distending the skin, which is very loosely fitted to the body, with air, blown into it through openings at the bottom of the cheek-pouches, which these animals possess. These openings are guarded by a circular muscle, which prevents the return of the air except at the will of the animal; and large valves for the same purpose exist in the neck and back. By this curious mechanism, the nycteris has the power of so completely distending the skin, as to give the idea of 'a little balloon furnished with wings, a head, and feet.' In this manner, the specific gravity of the body is diminished; and some other purpose may be answered by the contrivance, as in the case of the analogous air-cells of birds.

To the second family, the *Phyllostominæ*, belongs the celebrated *Vampire*, of the blood-thirsty propensities of which such marvellous stories have been told. The wound inflicted by its teeth is very small; but its tongue is endowed with a peculiar power of suction, by which a considerable amount of blood may perhaps be drawn. There are no well-authenticated accounts of the death of any animal having been occasioned by this creature; and the story of its fanning its victim with its wings to keep him cool, and render his sleep more profound, is probably a fiction of the imagination. Some of these bats have the tail very short, and in others it is altogether absent. They appear to feed in part upon succulent fruits; but there is one genus, the extreme shortness of whose intestine indicates that it must derive its food from animal matter almost exclusively. One of these has been taken in the act of sucking blood from the neck of a horse. The vampires are confined to South America; but other members of this family inhabit the Eastern Hemisphere. Many of them attain considerable dimensions; the body being equal in size to that of the magpie, and the wings, when expanded, measuring between two and three feet across.

The third family, *Vespertilionidæ*, is by far the most numerous, and includes most of the bats of temperate climates. At least thirteen species exist in this country, the largest of which is the *Mouse-coloured Bat*, the expansion of whose wings measures fifteen inches; but this is of rare occurrence. A more common one is the *Noctule*, or Great Bat, which is but little smaller; this is often met with in considerable numbers, seeking its retreat sometimes in the hollows of trees; at others, under the roofs and eaves of houses. Probably the most abundant is the *Long-eared Bat*, which is easily



Long-eared Bat.

distinguished by the character implied in its name. Its ears are folded downwards during hybernation or profound sleep. It is easily tamed when in confinement, and may be brought to considerable familiarity, so as to eat from the hand. It has an acute and shrill, but not loud cry.

The bats of the fourth family, *Noctilionidæ*, are almost exclusively confined to tropical countries. The number of species belonging to this group is very large, but few of them present any important peculiarities. One of the most interesting is the *Cheiromeles*, an inhabitant of Java and Siam, which has a distinct opposable thumb on the hind-feet, by which it can grasp small objects. It is, therefore, an evident connecting-link between the orders Cheiroptera and Quadrumana.

The Frugivorous or Omnivorous group contains but one family—the *Pteropinæ*. This is widely diffused throughout warm climates, and contains some of the largest species of the order. It is not improbable that

the fabulous harpy may have had its origin in some of these. None of them have the tail much developed, and in many it is entirely absent. The *Pteropus Javinicus* is a very characteristic example of this family. It is probably the largest of the bats—its expanded wings measuring five feet across. It is extremely abundant in the lower parts of Java, and uniformly lives in societies. They suspend themselves from trees during the day; and from their motionless aspect and contracted bodies, they might be mistaken for parts of the tree, or for fruit suspended from the branches. When night comes, they begin to move, and go in search of food to the forests, villages, and plantations; in all of these they do great mischief, attacking indiscriminately almost any kind of fruit, of which they devour a large quantity. In their turn, they are eaten by the human inhabitants of some of the countries where they abound, who consider them as delicacies. The flesh of the *Common Roussette* of the Mauritius has been compared to that of the hare and partridge.

The Cheiroptera inhabiting temperate climates all remain in a torpid state during the winter. Some of them make their appearance, however, in mild days; but as casual revivals during the season of repose are injurious to them, they usually betake themselves to places of which the temperature is not readily affected by external vicissitudes. The office of this group in the economy of nature is evidently to assist birds in restraining the too rapid multiplication of insects, and to keep down the luxuriance of tropical vegetation.

Quadrumana, or Monkeys.

The QUADRUMANA have an interest for us beyond most orders of Mammalia, on account of their being the animals nearest to man in external form and in intelligence. They are omnivorous animals, dwelling chiefly in the forests of warm countries, and spending much of their time on the branches of trees, among which they are well fitted to move by reason of the grasping power of their extremities. These are considered by naturalists as four hands—hence the name of the order—each hand having one finger opposed to the rest, like the thumb on the human hand. The two hinder hands, though resembling human feet, are not intended by nature to serve as a support to the entire weight of the animal. It only puts the outside to the ground, and seems awkward and insecure unless it has the fore extremities also employed in its support or in progression. The lowest of the monkey tribe have hands little advanced beyond the feet of the Carnivora, and even among the highest the organ is inferior to what it is in man. A corresponding series of gradations may be traced in the aspect of the face; for whilst, at one end of the series, the muzzle (at least in the young animal) is not much more prominent than it is in some races of man, at the other, it nearly resembles that of other Mammalia. Nevertheless, throughout the order, a certain degree of resemblance to man may be perceived in the gestures, as well as in the general aspect of these animals. All of them, like man and the Carnivora, possess three sorts of teeth; the canines, in the full-grown animal, are much more developed than in man; and there are intervals between them and the other teeth which are not present in his jaws, but exist in all other Mammalia.

The Quadrumana may be divided into three families —the *Simiadæ*, or *Monkeys of the Old World;* the *Cebidæ*, or *American Monkeys;* and the *Lemuridæ*, or *Lemur* tribe, which supply the place of monkeys in Madagascar and some parts of Africa and India. This restriction of distinct types of structure to different portions of the surface of the globe, is not a little remarkable; and it may be traced even in the subordinate divisions.

The *Simiadæ* must be regarded as the types of the Quadrumanous order; and amongst these the *Apes* manifest, in the most striking manner, the peculiar characters of the group. These are distinguished from the other subdivisions, in part by the absence of a tail, but also by the want of the cheek-pouches and of the callosities, or hard spots on their haunches, destitute of hair, which the monkeys and baboons possess; and further, by the predominance in length of the fore-feet or arms over the hinder ones. The most remarkable species of this group are the *Chimpanzee* and *Orang-outang:* the former, a native of equinoctial Africa; and the latter,

Chimpanzee.

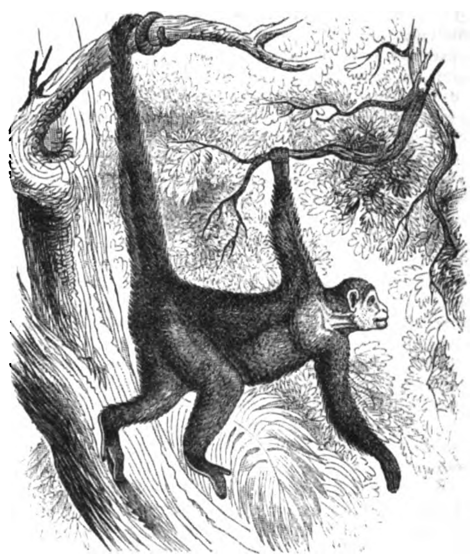
of the peninsulas and islands of Eastern Asia. Both these animals attain considerable size when full grown: the former rising to five feet, and the latter to seven; but no living specimens of those sizes have ever been seen in this country. In both, there is a remarkable difference between the young and the adult form of the skull—the young bearing the greatest resemblance to that of man, whilst in the adult the muzzle is so much prolonged, and the canine teeth are so much developed, as to give the face much more the aspect of that of the baboon. This difference, together with a change in the colour of the hair, has caused specimens of the Orang at different ages to be accounted distinct species. The character of the animal also changes, being mild and gentle when young, but having a good deal of baboon-like ferocity when come to its full development. In the *Gibbons*, or *Long-armed Apes*, the length of the anterior members is so great, that they touch the ground when the animal is in a semi-erect attitude; these present an approach to the monkeys, in the possession of callosities on the haunches by some of the species.

The *Monkeys* of the Old World are distinguished (in addition to the characters which separate them from the Cebidæ) by the possession of cheek-pouches, callosities, and a tail, which distinguish them from the apes; the tail is longer than in the baboons, the muzzle less protuberant, and the aspect less ferocious. The group contains, however, some species which present an approach to the apes, and others which form a transition to the baboons. The *True Monkeys* are also remarkable for the shortness of the arms in proportion to the legs, which causes some species to walk on all-fours with difficulty, climbing being their usual mode of locomotion; but by common observers they are still more noticed for the beauty of their colouring, their activity of movement, and gentleness of demeanour. Their character is much changed, however, by confinement. They are found in almost all the tropical countries of the Old World, and particular genera have a peculiar local distribution. Many of them live in societies, chiefly inhabiting the woods, but committing great devastations

on any cultivated ground in the neighbourhood. In several species, the aspect of the head is extremely grotesque, as are also the attitudes of the animal. Their food seems to be rather vegetable than animal; and in one genus this is distinctly indicated by the structure of the teeth and of the stomach. Another genus, restricted to Africa, is destitute of thumbs on the anterior extremities, and the deficiency is partly supplied by the great development of the tail, which is not, however, prehensile, as in the American monkeys.

The *Baboons* have usually a short tail, or none at all; but there is much variation in this respect. They are rather distinguished from the apes and monkeys by the protuberance of the muzzle, and the ferocity of aspect which is partly dependent upon this; the canine teeth are generally large and strong. The Baboons have also a large bag connected with the organ of voice, by the resonance of which the power of their loud and discordant cries is greatly increased. The animal commonly termed the *Barbary Ape* is in reality a baboon; but in the almost total deficiency of tail, it bears a superficial resemblance to the former group. A race of these animals inhabits the Rock of Gibraltar, where they manage to obtain a scanty subsistence. This is the only instance of the existence of Quadrumana in a wild state within the boundaries of Europe. The *Mandril* is the largest of the Baboons, and of the Quadrumana in general, with the exception of the chimpanzee and orang. It is a ferocious-looking animal, and is distinguished from other baboons by the bright red colour of its cheeks; it is dangerous from its size, strength, and uncertain temper, so as even to become a terror to the negroes of Guinea, of the woods of which part of Africa it is an inhabitant. The group of Baboons is almost confined to Africa and Western Asia. Dr A. Smith, a traveller in Southern Africa, states that they chiefly inhabit barren stony places, where they subsist, for the most part, upon scorpions, to procure which they employ their hands to lift up the numerous loose stones, under which one or more of these creatures commonly lie concealed: their stings they extract with dexterity. Baboons are by no means devoid of intelligence; but they do not seem capable of being steadily attached by kindness, and generally exhibit an alternation of moody sullenness and violent outbreaks of passion. Their resentment of injuries is often manifested for a long time afterwards.

The Monkeys of the New World, composing the family *Cebidæ*, differ from those of the Old, not only in the greater number of their grinders and a wider disposition of the nostrils, but in the entire absence of the cheek-pouches and callosities, and also in the conspicuous character of the tail, which is capable of being twisted round branches so firmly as entirely to support the animal. In general, the thumbs of the anterior members are not opposable; and they are sometimes scarcely developed at all. The Cebidæ are usually of smaller size than the Simiadæ, none of them attaining nearly the dimensions of the chimpanzee, orang, or mandril; they are also less malicious, more easily tamed, and susceptible of a more constant attachment; but they seem to possess less intelligence. They are found in very large numbers in the woods of South America, where they chiefly subsist on vegetable food, to which their teeth shew a peculiar adaptation. The largest of them are the *Myceti*, or *Howling Monkeys*, which derive their tremendous powers of voice from a sort of hollow drum connected with the larynx (somewhat resembling that of the baboons), which is peculiar to them amongst the Cebidæ. They are shaggy animals, about the size of a fox. The *Ateles*, or *Spider Monkeys*, are remarkable for the length and prehensile power of their tails, and for the absence (in some species entire, in others nearly complete) of the thumb; whence they are called four-fingered monkeys. A remarkable link, by which this group is connected with the Simiadæ, is afforded by the genus *Oustitis*, which includes the animals known as marmosets and tamarins. Like the American monkeys



Spider Monkey.

in general, they have the nostrils lateral, and the haunches covered with hair, and are destitute of cheek-pouches; but they have only ten grinders in each jaw, like those of the old continent. All their nails, except those of the hinder thumbs, are compressed and pointed, so as to assume the appearance of claws; and even the thumbs, though furnished with flat nails, are yet so slightly separated from the other toes, that the animals can scarcely be called 'four-handed.' The lower jaw possesses large cutting teeth, resembling those of the Rodentia—an order to which this group presents several points of resemblance. They are all diminutive animals, of pleasing forms, and very active movements; some of them are rather irritable in temper, and present an appearance which is really formidable, notwithstanding their size. There is another genus, *Pithecia*, which may be regarded as representing the baboons of the Old World among the Cebidæ; the tail being short, the head large, and the canine teeth much developed. Many of the species are strong, stout, and fierce; having a hoarse and hollow voice, and a malicious aspect. Some of them are nocturnal in their habits, and feed upon small Mammalia and birds, which they steal with great caution and noiselessness; such are distinguished by their large and prominent eyes.

The third family of Quadrumana, that of *Lemuridæ*, has in many respects the general aspect of the American monkeys; but the muzzle is much prolonged, resembling that of insectivorous or carnivorous animals; the teeth, also, are modified for animal food, presenting sharp tubercles, locking into each other; and the grinding motion of the lower jaw is reduced, so that its action possesses more of the scissor-like character of that of the animal-feeders. The four thumbs of these animals are well developed and opposable; the claw-like aspect of the nail of the first hind-finger is one of the most easily recognised characters of the family. The canines in the lower jaw have the character of additional incisors; and the first molars resemble the ordinary canines. The total number of teeth in each jaw is eighteen, as in the American monkeys. The *True Lemurs* are distinguished by their very large and handsome tails, which are elevated when the animals are in motion, and not trailed after them; they average the size of a large cat, but have

longer limbs. They are nocturnal or twilight animals, passing the day in sleep, rolled up in the form of a ball; at night they rouse themselves, and spring with the greatest activity in search of their food, which principally consists of fruits. They are entirely confined to Madagascar, where at least thirteen species are known to exist, differing from each other but little except in colour. On the other hand, the *Galagos*, which are found in the neighbourhood of the river Senegal, are pre-eminently insectivorous. With this group may be associated a very remarkable animal, which bears a strong resemblance to the sloth—the *Stenops Tardigradus*, or *Slow-paced Lori*, an inhabitant of India and the Eastern Archipelago. It has the teeth of the Lemuridæ, the short muzzle of a mastiff, a slender body, no tail, and large approximating eyes, as in the Lemurs. It subsists on insects, occasionally on small birds and quadrupeds. During the day, it sleeps, clinging to a branch, with the body drawn together; at night it prowls among the forest boughs in quest of food; its sight is then excessively acute, and it steals noiselessly on its victim. Its grasp is remarkably tenacious; and it has been found that the trunks of the arteries of the limbs subdivide, as in the true sloths, into a net-work of branches, the object of which seems to be to retard the blood in its passage amongst the muscles.

In this group may be placed two remarkable animals, which, from their strong resemblance to other orders, were associated with them by Cuvier and other naturalists. The first of these is the *Galæopithecus*, or *Flying Lemur*, which, from its strong resemblance to the bats, has been arranged with the Cheiroptera. It is, however, a *lemur* in all its essential characters; but it has its limbs connected by thin skin, which they stretch out, as the framework of an umbrella supports its covering. By this singular structure the animal is supported in the air, as by a parachute; but it has not the power of sustaining a continued flight, though it can leap a distance of a hundred yards with a gradual descent. Like the bats, it feeds on insects, and sleeps with its head downwards, suspended by its hind-legs. It is a native of the Indian Archipelago. The other of these aberrant forms is the *Cheiromys*, or *Aye-aye*, which, from the peculiar form of its two lower front teeth, has been ranged with the Rodentia. In its general character, however, it is essentially a lemur; the thumbs of the hind-feet are opposable to the other toes, which is not the case with any truly rodent animal; and approaches to a similar conformation of the teeth are seen in other lemurs. Moreover, it is a native of Madagascar, the centre of this group. It is a nocturnal animal, about the size of a hare: it is said to spend its day in holes in the ground (but these are probably not of its own excavation), and at night to climb trees, from the crevices in the bark of which it picks out worms and larvæ of insects with its long slender fingers.

Bimana.

At the head of the Mammalia, and consequently of the entire Animal Kingdom, stands the order Bimana, implying Two-handed Animals, but in reality composed of but one genus—Man. He may be comprehensively described as a being fitted to live upon almost all kinds of food, and in every part of the earth except those constantly under snow; of an extraordinary intelligence, and tendency to social life; eminent in power over all other animals, and endowed with the greatest ability to turn the objects and forces of physical creation to his own benefit. Besides all this, we believe there is a spiritual being within us, and vouchsafed to no other species, by which we are brought into peculiar relations to the Divine Author of nature, and which will survive the frail tenement in which we live.

In this place we have to consider man solely as a part of the Animal Kingdom. He is distinguished by an erect posture, and by the two fore extremities being fitted for prehension only, while the two hinder are devoted to support. By the upright position his upper extremities are left at entire liberty, whilst his organs of sense are most favourably situated for observation. The hand of man is adapted to a far greater variety of purposes than that of the monkeys in which it is most perfect; its power consists chiefly in the size and strength of the thumb, which can have its tip brought into opposition with that of any of the fingers; and all these are capable of being moved separately. In none of the monkeys can the thumb be opposed to the fingers with any degree of force, and in many their tips cannot be brought into contact; so that, though admirably adapted for clinging round bodies of a certain size, such as the small branches of trees, their hands can neither seize very minute objects nor support large ones. To the hand of man some have attributed his superiority; but it may be safely said, that he owes this to his mind and its instruments conjointly. The hand would be useless without the mind to direct it; and mankind, if handless, would soon be reduced to a very subordinate kind of existence, if not speedily extinguished altogether.

Man, possessed of so remarkable a means of executing that which his mental ingenuity devises, is less provided, in regard both to acuteness of sensibility and to muscular power, than many other Mammalia. His swiftness in running is inferior to that of other animals of his size. The smallness of his face, compared with that of the cranium, shews that the portion of the nervous system connected with the external senses is less developed in him than in most other animals. Accordingly, he is surpassed by many in the acuteness of his sensibility to light, sound, &c. But he stands alone in the power of comparing his sensations, and drawing conclusions from them. Moreover, although none of his senses are very acute in his natural state, they are all moderately so, which is not the case in other animals; and they are capable (as is also his swiftness of foot) of being much improved by practice, especially when circumstances strongly call for their exercise.

This improvability is one of the most remarkable characteristics of the bodily as well as the mental constitution of man. It is owing to a gradual advance in both, that the civilised races now enjoy so much of comfort, and of means of still further elevation. In the processes by which these are attained, we observe a remarkable difference between the character of man and that of other animals. The arts of which these are capable are limited and peculiar to each species; and there seems to be no evidence of a power of invention, or of construction for any purpose, beyond that to which the original and instinctive powers are adapted. Hence it would appear, that there is no proof of any species or race among the lower animals ever making an advance towards an improvement or an alteration in its condition; and where a particular adaptation of means to ends, of actions to circumstances, is made by an individual—as is often the case where some amount of intelligence or rationality exists—the rest do not seem to profit by it.

Man is as much distinguished, then, from the lower animals by his mental as by his corporeal endowments. Yet they are not of a *kind* altogether different from that which we may elsewhere see. In common with the inferior tribes, he possesses strong instinctive propensities, which are kept under control, however, in a well-balanced mind; but when the reasoning powers are undeveloped, as in early childhood and idiocy, the exclusive sway of the instincts is obvious. The more violent passions and emotions are nearly akin to these; and whilst they give great activity to the operations of the mind, it is requisite that they should be duly restrained by the intellect and will. This power of internal regulation is one of the most striking characteristics of the human mind above that of animals, which possess like it reasoning faculties, often to no mean extent, and are actuated by emotions and moral feelings.

One of the most important aids to the use and development of the human mind, is the power of producing articulate sounds, or language; of which, so far as we know, man is the only animal in possession. There is no doubt that many other creatures have certain powers of communication amongst individuals; but these are probably very limited, and of a kind very different from a verbal language.

The more we study the physical and mental constitution of man, the more are we led to the belief, that it is in the adaptation of the whole to a great variety of circumstances that its great perfection consists. There seems scarcely any condition in which he cannot support himself; he is capable of sustaining the lowest as well as the highest extremes of temperature. Furnished with cutting, canine, and molar teeth, he is clearly fitted for a mixed kind of diet; but he can support himself in health and strength on either animal or vegetable food exclusively. At the same time, it is by the demands which his peculiar condition makes upon the exercise of his ingenuity that his mental powers are first called into active operation; and when once aroused, their development has no assignable limit. On a cursory glance at the condition of the inhabitants of different parts of the earth, it will almost always appear that where food and shelter are the most easily obtained, civilisation is the least advanced. Frequently, as in many Eastern nations, a certain progress is early made, and the race then remains stationary for centuries.

The striking differences in colour, in the form of the head and other parts of the body, and in degree of intelligence amongst the different races of men, have caused some naturalists to regard them as constituting distinct species—that is, as being descended from original stocks having corresponding differences from each other. But this notion does not appear reconcilable with the fact, that in each race there not unfrequently exist subdivisions, of which the characters approximate more closely to those of other races than is ever seen among distinct species.* For example, although a characteristic specimen of the Negro race is extremely different from a well-formed European, a series of nations might be traced in Africa whose common origin can scarcely be questioned, and which yet lose one Negro peculiarity after another, until a very close approach is manifest to the character of the white races.

Again, it is to be remarked, that the differences among the races of men are such as are observed in other animals to result from the influence of external causes, or to have a spontaneous origin; whilst in those points which most completely separate him from the species most nearly allied, there is a thorough conformity. This is especially the case in regard to his mental endowments; for similar natural prejudices and impressions, the same feelings, sympathies, and propensities, and intellectual faculties corresponding in kind, if not in degree, may be traced in all of them.

Nevertheless, the different races peopling the earth may be associated into groups, from their greater or less resemblance to each other; these groups having probably been distinct from a very early period, and their members usually having affinities in language as well as in physical conformation. Five of such groups are usually described.

The first occupies Europe and the south-western part of Asia, and may be geographically divided from the second by a line passing eastwards from the Euxine through the Caspian, then following the direction of the Himalaya mountain-range, and descending to the Gulf of Bengal. The two great regions thus separated have been from the earliest periods the abode of two great classes of the human race, differing from each other in manners and social character, as remarkably as the arid and saline plains of Mongolia and the cold desert of Gobi differ from the warm and fertile countries of Southern Asia.

To the western group (commonly termed Caucasian) the name of *Iranian* is applied by Dr Prichard, the highest authority on this subject. The nations composing it people India, Persia, and Arabia, the north of Africa, and nearly the whole of Europe. In the inhabitants of this space, a similar configuration of body may, with few exceptions, be recognised. Of this, the ancient Greeks seem to afford the most perfect model. It is principally remarkable for the roundness of the cranium and the oval form of the face, and for the small proportion which the latter bears to the former, the upper and anterior parts of the brain being chiefly developed. The muzzle does not project, the front teeth of both jaws being perpendicular; the lips are gently turned out, the chin full and rounded. Complexion does not enter into the characters of this group; since it is of all shades, from the white and florid colour of the northern Europeans, to the jet black of many tribes in Libya. In these Indo-Atlantic nations, we find the greatest energy of the intellectual powers and moral feelings, and the greatest susceptibility of improvement by culture. They certainly, therefore, rank highest in the human family. It seems probable that the region of Upper Asia termed Iran, was the primitive seat of those families of nations who have most extensively spread the same type of features.

The nations inhabiting the northern and eastern parts of Asia, with the Finnish nations of Northern Europe, and the Esquimaux of North America, evidently belong to a different group (commonly called the Mongolian), to which Dr Prichard has given the appellation *Turanian*. These are particularly characterised by the form of the skull and face, which seem as if they had been flattened in front; so that the features run together. The cheek-bones project very far sidewise; the nose is small, and flat; the lips rather thick; the chin less projecting. The characteristic complexion of this group is olive; the eyes are usually black; and the hair black, straight, and strong, but thin. The forehead is low and flat. Their stature is generally lower than that of Europeans; and, with greater acuteness of the senses, they exhibit less intellectual power.

The general characters of the Negro races inhabiting the tropical parts of Africa are sufficiently well known. Their complexion and eyes are dark, approaching more or less closely to black; the hair black and woolly. The skull looks as if it had been compressed laterally, so as to cause the face and back-head to project. The forehead is low, narrow, and slanting; the jaws narrow and projecting; the upper front teeth oblique, and the chin receding; the nose is broad and flat; the lips, especially the upper one, thick. It cannot be denied that in these characters the Negro head is intermediate between that of the European and that of the monkey; but it far more nearly resembles the former than the latter. It is a very important fact, also, that it is only in the most degraded African races that we meet with the *whole* assemblage of characters regarded as distinguishing the Negro; and that in others we find so strong a tendency towards a higher character, that it would be difficult to distinguish many individuals among them from others that might be selected from the Iranian race. The influence of climate, and other external circumstances, on the physical and mental development of the human body, is nowhere more evident than when the degraded nations of the Guinea coast are contrasted with the intelligent Caffres of the south or the civilised Ashantees to the north. There can be little doubt, then, that no decided lines separate the African from the European races; and that the former may, in process of time, be brought up to the same intellectual and moral standard with the latter.

According to Dr Prichard, the Hottentots and Bushmen, inhabiting the south of Africa, must be regarded as constituting a distinct group, in which human nature

is exhibited in its most degraded form. There is a remarkable admixture in their physiognomy of the characters of the Negro and Turanian races. The face is extremely flat; the nose has scarcely any perceptible ridge, and its extremity is greatly widened; the eyes are placed very obliquely, as in the Chinese; the chin is prominent, but very narrow; the complexion is like that of a Negro, diluted with yellow; the hair grows in separate tufts, which spontaneously twist together. In their language, the Hottentots seem to have no affinity with the other nations of South Africa which had a Negro origin; and they live in a more destitute and miserable condition than any other inhabitants of this continent.

The aboriginal nations of America, excluding the Esquimaux and some other tribes, form a well-marked division of the human family, bearing a strong general resemblance to each other in their most remarkable characters, both physical and moral. As in the Iranian division, the complexion varies extremely; but in general a reddish or copper hue prevails. The form of the head more resembles that of the Turanian group than any other.

Caucasian.

Arab Moor.

Mongolian.

Otto Indian of N. America.

Negro (pure type).

Malayan.

Central American Indian.

Bushman (of S. Africa).

Native of Tasmania.

Native of Tierra del Fuego.

The Indian and Polynesian archipelagoes are inhabited by a great variety of nations, which have probably had mixed origins, and which it is difficult, therefore, to refer to any single group. Two races, however, appear to be decidedly distinct from the rest. One of these consists of the genuine Papuas, or woolly-haired inhabitants of the interior of New Guinea and the adjacent large islands. These bear a strong resemblance to the people of Madagascar. Their hair is less woolly, is longer and thicker than that of the Negroes, but is very different from the lank hair of the Malays and other races. The other, that of the Alfourous, appears to have constituted the primitive population of the Eastern Archipelago, but is now nearly confined to the interior of Australia. The hair is not woolly, but hard, black, and thick. The countenance is flattened, and the nose so wide that the nostrils are almost transversely placed. The lips are thick; the mouth wide; and the teeth projecting. The colour of the skin is of a smoky black, never very deep. The stature is usually below the mean; and the limbs seem of disproportioned length. Their physical and mental development appear altogether extremely low.

NATURAL PHILOSOPHY—MATTER AND MOTION.

As man contemplates the bodies that make up the universe, and the endless movements and changes they undergo, he becomes impressed with the conviction that these *phenomena* (appearances), as they are called, are not simply a collection of individual things ruled by chance, but that there are fixed connections—in other words, order and uniformity among them; and he feels irresistibly impelled to trace out these connections wherever they can be discovered. In this pursuit we have Natural Philosophy in its widest sense.

When we have found out an unchangeable link of connection between two or more phenomena, we are said to have discovered or established a *law* of nature. It is observed, for instance, that whenever matter is heated, it becomes enlarged in bulk; it is therefore recorded as a law of nature, that 'heat expands bodies.' When, again, we can shew that some other phenomenon, seemingly widely different, is really, though indirectly, caused by the operation of the same law, we are said to *explain* that phenomenon. Thus we explain the fact that a clock is apt to go slower in summer than in winter, by first establishing that a clock goes slower the longer the pendulum is, and then inferring from the law of expansion by heat, that the pendulum must be longer in summer than in winter.

Some phenomena depend upon the peculiar kind of substance of which the body manifesting them is composed, and consist in changes of its constitution; as when sulphur, at a certain temperature, takes fire—that is, unites with the oxygen of the atmosphere, and forms a suffocating gas, changing permanently its constitution and properties. The facts of this class form the separate science of *Chemistry*. Organised bodies—that is, plants and animals—also manifest a peculiar set of appearances which are summed up in the word *life*. The consideration of *vital* phenomena belongs to the department of science called *Physiology*, sometimes *Biology*.

But there is a large and important class of phenomena of a much less special kind, and which belong to matter in general, and to all bodies composed of it, whatever be their peculiar constitution, and whether organic or inorganic. Thus, a stone, a piece of sulphur, a plant, an animal, all fall to the earth if unsupported, are all capable of being divided into small parts, all reflect more or less light, &c. It is the investigation of universal laws of this kind, where no change of constitution is concerned, that constitutes Natural Philosophy, in its narrower sense; for which the term *Physics* is now more generally used, as being more precise. Of those physical phenomena, again, some have a higher generality than others, and it is these most general laws of the material world that naturally fall to be discussed in this introductory treatise. They may be arranged under the heads of *General Properties of Matter*, *Motion and Forces*, and *Heat*.

GENERAL PROPERTIES OF MATTER.

Matter, or that which composes all bodies, has certain *properties*; by which is meant, that it has the power of making certain impressions upon our senses, or of exciting in us *sensations*. Through these sensations we are said to have a *perception* of matter and bodies; but as to what matter is in itself, beyond its power of affecting our senses, we know nothing. The something, whatever it is, in which this power is conceived to reside, is called *substance*. Some philosophers deny the existence of anything beyond the properties; but though we have no direct evidence of anything else, it is difficult, if not impossible, to get rid of the notion, that there is a substance in which the properties inhere. So far as natural science is affected, the question is of no moment; what really concerns us is how matter appears and acts, and not what it is. The more important of the properties of matter are—Impenetrability, Extension, Divisibility, Inertia, Porosity, Compressibility, Elasticity, Attraction, States of Aggregation, Malleability, &c. We shall describe and illustrate them in succession, classing such qualities together as seem to be naturally connected.

Impenetrability is that quality of bodies by virtue of which each occupies a certain portion of space, to the exclusion of all other bodies; it expresses the fact that two bodies cannot be in the same place at the same time. The term impenetrability is not a happy one, though it is difficult to find a better. In the popular sense of the word, matter is anything but impenetrable. The hand can be thrust into water, a nail can be driven into wood, and even the hardest substances are pierced by others that are more or equally hard. But all these are instances merely of displacement, or of removing part of one body to make room for another. There is no wood where the nail is, nor are the particles of the removed wood driven into one another, so to speak; they are merely forced closer together, as those of a sponge are when squeezed. That the most movable and unsubstantial substances, when displacement is prevented, occupy space as effectually as the most solid, is seen in a blown bladder, or in an air-cushion. This property of air is taken advantage of in the diving-bell. An easy illustration is got by pressing a common glass tumbler, mouth downwards, into a vessel of water. Though the water ascends more or less according to the depth, the air makes good its claim at ordinary depths to the greater part of the space, and even though sunk to the bottom of the sea, the water would never get quite to the top. If a small lighted taper, floating on a bit of cork, be carried down with the tumbler, the singular appearance may be beheld of a light burning under water.

Extension or *Magnitude*, and *Form*.—Magnitude or size is one of those simple ideas that do not require or admit of explanation, because there is nothing simpler to explain them by. It is chiefly by their extension that bodies make themselves known to our senses; and when we try to think of those minute particles of matter that elude the senses, we can conceive them only as extended, or having a certain magnitude. Bodies are extended in three directions, or have three *dimensions*—namely, length, breadth, and depth. Width is the same dimension as breadth; and for depth we often use height, and sometimes thickness. The way in which these dimensions are bounded gives each body its peculiar form or shape. This is equally true of a block of stone, a sheet of paper, a hair, a particle of dust.

Divisibility.—There is no known limit to the divisibility of matter. A chip of marble may be broken from a block, and that chip may be crushed to powder. The smallest particle of this powder discernible by the naked eye, when examined by the microscope, is seen to be a block having all the qualities of the original marble, and capable, by finer instruments, of being divided into still smaller blocks, which may be again divided; and so on, with no other limit than the fineness of our senses and instruments.

The unlimited degree to which matter may be

comminuted is yet more strikingly seen in other ways. The goldbeater produces leaves, of which there are 282,000 in a pile of an inch deep. In making the gilt silver-wire used in embroidery, a rod of silver is covered with a small proportion of gold, and then drawn out to a fine wire, in which the gold retains the same proportion to the silver as at first. A portion of this wire, on which the gold is only the 482,000,000,000th part of an ounce, may be seen by a microscope to be covered with a continuous coating of the metal, having all the appearance of solid gold. The thinness here far exceeds that of goldleaf.

Still more minute must be the division when a substance is dissolved in a liquid, or water rises in vapour, since the particles in this case become so minute as to be invisible with the most powerful magnifiers. The microscope, again, has revealed the existence of animals, a million of which would not occupy more space than a grain of sand. Yet these animalcules, as they are called, have limbs and organs, and display all the appearances of vitality. How shall we conceive the smallness of the tubes or vessels in which their fluids circulate, and the minuteness of the particles of matter composing these tubes and fluids!

Divisibility thus extends far beyond the limits perceptible to the senses. Are we, therefore, to assume that it is without limits—that matter is infinitely divisible? This would be a rash assumption. On the contrary, there are many reasons for believing that there is a limit somewhere, and that there are ultimate particles, of a determinate size and shape, incapable of further subdivision. These assumed ultimate particles are called *atoms*, from a Greek word signifying indivisible. Their existence is inferred from a number of facts connected chiefly with crystallisation and chemical combination, which cannot be otherwise explained.

But whether the ultimate component particles of bodies have a fixed size and shape or not, we know that they are *indestructible*. This is not, indeed, what a first impression suggests, for nothing is more common than for bodies to decay, dissolve, evaporate, and disappear. But it can be proved that in no case is anything lost. The structure or form is destroyed, the materials remain. Water, mercury, and many other substances disappear in invisible vapour when heated; but if the vapour is carefully collected and cooled, the water or mercury reappears without loss of weight. The substance of the coal burnt in our fires is not annihilated; it is only dispersed in the form of smoke or particles of soot, gas, and ashes or dust. Bones, flesh, and other animal substances, may in the same manner be made to assume new forms, without losing a particle of the matter which they originally contained.

The decay and decomposition of animal and vegetable substances beneath the surface of the earth fertilise the soil, which nourishes the growth of living plants; and these, in their turn, form the nutriment of animals. There is thus a perpetual change from death to life, and from life to death, and as constant a succession in the forms and places which the particles of matter assume. Nothing is lost, and not a particle of matter is struck out of existence. The same matter of which every living animal and every vegetable was formed in the earliest ages, is still in existence. As nothing is lost or annihilated, so it is probable that nothing has been added, and that we ourselves are composed of particles of matter as old as the creation. In time, we must in our turn suffer decomposition, as all forms have done before us, and thus resign the matter of which we are composed to form new existences.

Inertia or *Inactivity*.—This is one of the most important qualities of matter, and deserves careful consideration from the number of phenomena it enables us to explain. It is at the foundation of nearly all that concerns motion and forces. The term inertia or inactivity is meant to express the fact, that an inorganic body has no power to change its state. If it is at rest, it cannot put itself in motion; if it is in motion, it cannot bring itself to rest; any change must come from some external cause. It hardly gives a correct notion to say that bodies are quite passive to a change of state; for they *resist* the change, with a force depending upon the mass of matter they contain and the amount of motion sought to be given to them or taken away. The expression *vis inertiæ*, force of inactivity, though involving a sort of contradiction, is sometimes used to indicate this quality of resistance. No one term conveys all that is meant; *persistence* has been suggested as less objectionable than inertia, inactivity, or passiveness. Bodies may be said to have a tendency to persist in their actual state, whether of motion or rest.

The following instances illustrate the action of this property of matter:—A great force is necessary at first to set a vehicle in motion; but when once this is effected, it goes onward with comparative ease; so that, in fact, a strong effort is necessary before it can be stopped. If a person be standing in it when it is suddenly set agoing, his feet are pulled forward, whilst his body, obeying the law of inertia, remains where it was, and he accordingly falls backwards. On the other hand, if the vehicle be suddenly stopped, and the individual be standing in the same position as formerly, the tendency which his body has to move forward—for it acquired the same motion as the carriage by which it was borne along—will cause him to fall in that direction. Casualties of this description frequently occur to persons on horseback, who are thrown over the necks of their steeds, or fall behind them, according as the animal stands still suddenly, or starts off unexpectedly. A man jumping from a coach at full speed will certainly fall prostrate on the ground, if he leaps down as if he were descending from a body at rest, to one which is in the same state; for when he makes the attempt, his body has the same motion as the coach; and when the feet arrive at the ground, the motion in the lower part is arrested, while it continues in the upper part; and thus he finds himself thrown down.

Another familiar example of the inertia of matter is this:—Upon the tip of the finger let a card be balanced, and a piece of money—say a shilling—laid upon it. Let the card then be smartly struck, and it will fly from beneath the coin, leaving it supported upon the finger. This arises from the inertia of the metal being greater than the friction between it and the card.

The process of beating a carpet, or dusting a book, rests on the same principle as the experiment with the shilling and the card. The carpet being struck, is suddenly put in motion, while the particles of dust remain where they were, their inertia being sufficient to overcome the slight force with which they adhere to the surface of the carpet. When a dusty book is struck against a table, the book and the dust are first brought into rapid motion together, and the book being then arrested by the table, the dust continues in motion by its inertia, and is thus detached.

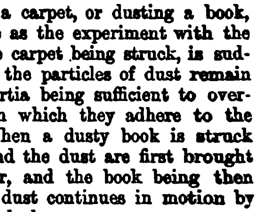


Fig. 1.

Coursing, or hare-hunting, affords a striking illustration of inertia. In that field-sport the hare seems to possess an instinctive consciousness of the existence of this law of matter. When pursued by the greyhound, it does not run in a straight line to the cover, but in a zigzag one. It *doubles*; that is, suddenly changes the direction of its course, and turns back at an acute angle with the direction in which it had been running. The greyhound being unprepared to make the turn, and therefore

unable to resist the tendency to persevere in the rapid motion which it has acquired, is impelled a considerable distance forward before it can check its speed, and return to the pursuit. But, in the meantime, the hare has been enabled to shoot far ahead in the other direction; and although a hare is much less fleet than a greyhound, by this scientific manœuvring it often escapes its pursuer.

It is a common impression with those who have never reflected upon the subject, that bodies are more inclined to rest than to motion. This arises from the fact, that while no body begins to move or increase its speed, without some cause for the change being apparent, all the motions that come within our observation on the surface of the earth do actually come to an end, most of them gradually, and without any very apparent cause. Thus the notion is begotten that rest is the natural state to which all matter, when left to itself, seeks, as it were, to return. But a little consideration shews us that the retardation and stoppage of motion are as dependent on causes as its beginning is. A ball rolled on the rough earth soon stops; on a wooden floor, it continues longer; and on smooth ice, longer still. This shews that one cause of the arrest of terrestrial motions is friction. Another constant impediment is the resistance of the air. A common top continues to spin a greater length of time in a space from which the air has been extracted by an air-pump, than it usually does. A pendulum set in motion in an exhausted receiver, will continue to swing, without the help of clock-work, for a whole day, having nothing to resist its motion but the small amount of friction at its point of suspension. Finding thus that motion is prolonged in proportion as we diminish obstructions to it, though we can never completely remove them, we conclude, that if they were removed, motion once begun would go on for ever.

It is in the heavenly bodies, however, that we find complete proof of this truth. They move without friction, and unresisted by any fluid like air, and no observation can detect any slackening of their speed; they retain the amount of motion they had from the beginning.

Compressibility, Contractibility; Expansibility, Dilatability.—When a body is forced by mechanical pressure into less space than it previously occupied, it is said to be *compressed;* when any cause not mechanical, such as loss of heat, causes its volume to diminish, it is said to be *contracted.* *Expansion* and *dilatation* are used to express enlargement of volume or bulk. Now, all bodies whatever are liable to these two opposite kinds of change—to have their volume, from a variety of causes, at one time enlarged, at another time diminished, and that without any addition to, or deduction from, the matter composing them. To say nothing of sponge, cork, wood, &c., the compressibility of which we experience every day; even those substances which we consider as types of solidity, are compressible. A piece of iron, when squeezed in a vice or hammered, loses in bulk, and becomes more compact.

The most compressible substances are air and other gases. A moderate pressure will force a quantity of air confined in a vessel into half its volume; and as the pressure is increased, the volume goes on diminishing almost without limit. By pressure and cold combined, several gases have been reduced to the liquid form. Compared with gases, or even solids, liquids have little compressibility. For all practical purposes, they are assumed to be completely incompressible, and water is so considered in hydrostatics and hydraulics. But experiment has proved this not to be strictly true; for, when submitted to a pressure of 15,000 pounds on the square inch, water is found to lose 1-20th of its volume.

Expansion or dilatation is chiefly seen in the case of heat being applied to bodies (see page 205). Gases are unlimitedly dilatable. If a room were completely exhausted of air, and a cubic inch of any gas introduced, it would instantly diffuse itself through the whole room, so that no space, even the smallest appreciable, would be completely void. The only reason why the air of our atmosphere does not diffuse itself throughout space, is that it has weight, which sets a limit to its dilatation.

Elasticity.—Some bodies, when compressed, recover their former size when the pressure is removed. Such bodies are called *elastic;* and those which remain as the compressing force put them, are *non-elastic.* Air and other gases afford the best examples of elasticity. Caoutchouc, ivory, and steel, are among the most elastic of solid substances. But no solid body is perfectly elastic, nor are any completely non-elastic; so that elasticity may be considered as general a property of matter as compressibility. The cause of elasticity is not well understood; it is supposed to be some peculiar relation between the forces of attraction and repulsion among the atoms.

Porosity and *Density.*—In common language, a pore is a small hollow space or interstice between the particles of a body, large enough to be seen, or to admit the passage of liquids or gases. In this sense, some substances, such as sponge, wood, sugar, &c., are called *porous,* and others are contrasted with them as *solid.* But experiment and reflection lead us to the conclusion that all bodies are porous. We have seen that bodies are made up of indefinitely small atoms; and the fact that all bodies admit of compression and expansion, makes us believe, that in no case do these atoms fill the whole space occupied by the body, but have interstices of greater or less size between them; so that when a body is compressed, its atoms are only more closely packed. There is nothing, then, that is not porous, in this sense; and one body is more dense or solid than another, only because it is less porous. *Density* thus means the comparative closeness of the atoms of a body; and a dense body contains, bulk for bulk, more atoms, that is, more matter, than one that is less dense, or, in other words, more porous. As weight depends upon the quantity of matter, density and weight thus go together.

In comparing the densities of different substances, that of distilled water is taken as a standard, and called 1. If a cubic inch, then, of any substance weigh twice as much as a cubic inch of water, its comparative density is expressed by 2; and this is generally called its *specific gravity.* The following table exhibits the specific weights of a few of the more familiar substances :—

Platinum, coined, .	22·100	Porcelain, china, . .	2·384
〃 wire, .	19·267	Sulphur, natural, .	2·033
Gold, coined, . .	19·325	Ivory, ...	1·917
Mercury, . .	13·598	Boxwood, ...	1·330
Lead, ...	11·352	Oak, old, . . .	1·170
Silver, . . .	10·474	Amber, ...	1·078
Copper, hammered, .	8·878	Mahogany, . . .	1·060
〃 fused, .	7·788	Milk, ...	1·030
Steel, ...	7·816	Sea-water, . . .	1·026
Iron, wrought, .	7·788	Water, distilled, .	1·
〃 cast, . . .	7·207	Claret, ...	·994
Tin, ...	7·291	Alcohol, absolute, .	·793
Antimony, . . .	6·712	Linseed Oil, . . .	·953
Diamond, . . .	3·520	Ash-wood, dry, . .	·644
Flint Glass, . . .	3·375	Beech, dry, . . .	·590
Marble, ...	2·873	Cork, ...	·240

Porosity, even in the sense of admitting the passage of liquids and gases, exists to a greater extent than is generally supposed. If a wooden cask full of spirits is sunk in water for a time, the cask will be found filled with water, and the spirits gone. The spirits escape, and the water enters through the pores of the wood. A hollow globe of gold filled with water, and closed with a screw, was once submitted to great pressure; when the surface of the gold became covered with dew, the water being forced through its pores. The important process of filtration depends on porosity.

Attraction and *Repulsion.*—The term attraction is applied to a great many phenomena, which we must regard as of different kinds, or produced by different causes. The force, whatever it is, that makes a stone

fall to the earth, is called the *attraction of gravitation*, because it is the cause of *gravity* or weight. Sir Isaac Newton demonstrated that the same force acts on the moon, drawing it towards the earth; and on the earth, drawing it towards the sun: or rather, that the attraction between any two heavenly bodies is mutual, making them approach each other. It is now established as a fundamental law, not only of our globe, but of the universe, that every atom of matter is attracted towards every other atom. The effects of this law, in causing the fall of bodies and weight, will be considered under Terrestrial Gravity in this number. (See also ASTRONOMY.)

When a loadstone or a magnetic needle is brought near to a piece of iron, the two bodies, if free to move, will come together and adhere to each other. Also, if a stick of sealing-wax is rubbed with silk, it will draw a light feather to it. These two forms of attraction—the *magnetic* and the *electric*—will be particularly described in the number on ELECTRICITY and MAGNETISM.

The kinds of attraction already mentioned act between bodies at a distance, as well as near. We know, for instance, that gravitation retains Neptune in his orbit at the distance of 2854 millions of miles from the sun. But there are forces at work in matter which act only at insensible distances, and between the adjacent molecules; they are hence called *molecular forces*. These play an exceedingly important part in nature, being the causes of a number of the most interesting phenomena. They are spoken of under the names of Cohesion, Adhesion, Repulsion, and Chemical Attraction.

Cohesion is that force that binds together particles of the same kind of matter, so as to form masses or bodies. Without some force to hold the atoms or molecules together, we could not have bodies, but mere heaps, as of sand. Some of the ancient philosophers imagined that atoms were provided with hooks, that made them stick to one another. But as we now know that distant bodies act upon one another with nothing between—draw one another, as it were, without ropes—we can conceive atoms holding one another, when near, without hooks. Cohesion acts only when the atoms are at distances so minute as to be insensible to us: when removed beyond that distance, it has no influence whatever; and when the atoms of a solid body are once separated, it is in most cases impossible to bring them near enough again to make them cohere. Two fresh cut surfaces of lead may be made to cohere with some force; but a slight film of rust or of grease will completely prevent the necessary nearness of the metallic molecules. Interrupted cohesion is easily restored when the body is in a fluid or half-fluid state, owing to the mobility of the molecules; as when a broken stick of sealing-wax is mended by melting the two ends and pressing them together, or two pieces of iron are joined by welding.

The three *states of aggregation*, as they are called—that is, the *solid*, *liquid*, and *aëriform*—are owing to differences in the strength and manner of acting of cohesion. It is commonly said that its force is greatest in solids, less in liquids, and altogether wanting in gases. But this account does not explain all the differences of these states. If the smallest quantity of air, or any other gas, is admitted into the exhausted receiver of an air-pump, it does not remain at the bottom, but spreads itself instantly and uniformly through the whole space, as if its particles wished to remove from one another as far as possible. There seems no limit to the space over which the smallest portion of gas will thus spread itself, so that it shall be found in every part of it. We cannot help inferring from this, that the atoms of a gas, instead of attracting, actually *repel* one another with a force sufficient to overcome their own weight—for gases have weight as well as solids and liquids. The dilatation of solid bodies by heat, and the recoil of elastic bodies after compression, would also seem to imply some repulsive force at work.

Again, some gases, when compressed with great force, have their atoms forced so near that they become liquid; and in this condition they are seen to cohere and form drops, thus shewing that they are not destitute of attractive force. The natural conclusion from these and other observed facts is, that among the atoms of all bodies there are two opposing forces at work—an attractive force, and a repulsive force—that when attraction considerably predominates over repulsion, a solid body is the result; when there is almost a balance of the two forces, we have a liquid; and when the repulsive force has the upper hand, we have a gas. Many substances are seen to assume all three forms in turn. Liquid water turns at one time into solid ice, at another into vapour or steam. Greater extremes of cold and heat have the same effects on mercury. Several gases, by applying great pressure and cold, have been rendered liquid, and one at least even solid; and thus it becomes probable that all substances are capable of existing in any one of the three states under certain conditions.

From the fact that the increase of heat regularly increases the energy of repulsion, heat and the repulsive force may be considered one and the same thing. The subject of HEAT will be more fully considered under a separate head.

In solids, the cohesion is exerted in such a way as not only to keep the atoms from separating, but also to retain them in the same relative position; in liquids, on the contrary, the atoms, while still kept from separating, are allowed to move or slide freely upon one another in all directions. This free motion of the molecules upon one another, rather than want of cohesion, is the grand characteristic of liquids as well as gases; it is one of the causes of drops being spherical. Differences of cohesion give rise to such distinctive qualities of bodies as the following:

Hardness.—This quality depends not so much upon the force with which the particles resist separation, as upon their resisting displacement or alteration of relative position. Softness implies the opposite. Hardness is tested by one body scratching another. It does not correspond with density. Thus, glass scratches gold, and even platinum. Steel has its hardness modified by tempering.—*Malleability* is a distinguishing quality of some metals, and means the capability of being extended into thin plates or leaves by hammering. It depends upon the union of softness and tenacity; the particles shift their position without separating. The chief malleable metals are gold, silver, copper, iron, zinc at the temperature of boiling water, and lead. Gold may be reduced to leaves so thin as to be translucent.—*Ductility* is the property by which a metal admits of being drawn into wire. The most malleable metals are not the most ductile. Iron is much more ductile than tin or lead, though not so malleable. The most ductile metal is platinum.—*Tenacity* expresses the quality by which a body resists being torn asunder, and depends upon the intensity of the cohesive force. It is not the opposite of *brittleness*. Brittleness is associated with hardness and unyieldingness, except within narrow limits. Glass is brittle—that is, is easily broken by bending or crushing—but a glass-rod will sustain a great weight without being *torn* asunder. Thus it is both brittle and tenacious. Fibrous substances—as silk and flax—possess great tenacity. The most tenacious of all substances is steel.

Adhesion, or, as it is sometimes called, heterogeneous cohesion, is the term applied to the attraction which makes two different substances stick to one another by their surfaces. Cohesion acts between the particles of the same kind of substance; adhesion, between dissimilar kinds of matter. Though the same force probably causes both, yet the effects are so different that it is convenient to consider them separately, and give them different names.

Adhesion between solids.—Particles of dust on an upright pane of glass, chalk-marks on a wall, sealing-

wax on paper, cement, are all instances of adhesion between substances of different kinds. Two polished plates of brass laid on one another, require considerable force to separate them. (Strictly speaking, this is a case of cohesion; but where the attraction is between the surfaces of two distinct bodies, it may be considered as adhesion, notwithstanding that the matter is of the same kind in both.) If one of the plates be of steel, the adhesion will be less; and generally similar surfaces adhere more than dissimilar. Adhesion between surfaces is the chief cause of friction, and unctuous substances are interposed to prevent it.

Adhesion of liquids to solids takes place much more readily than that of solids to solids, because in the case of a liquid and a solid the surfaces come into more complete contact. When the hand or a rod of metal is dipped into water, a film of the water adheres to the surface, and is borne up against its own weight; nor can any force shake it all off. Plunge a bit of gold, or silver, or lead, into mercury, and a portion of the mercury will in like manner adhere. Wherever we have *wetting*, we have a case of adhesion of a liquid to a solid. It is the cause that in pouring water over the edge of a vessel, the water is apt to run down the side of the vessel rather than fall perpendicularly.

But liquids do not always wet solids, or adhere to them. A rod coated with grease, or the wing of a water-fowl, remains dry when plunged in water. Mercury does not adhere to a porcelain cup, or to a rod of iron or platinum. The explanation is simple. There is in every case an attraction between the solid surface and the liquid, but it is opposed by the attraction of the particles of the liquid for one another, and there can be actual adhesion only when the first is stronger than the other.

Capillary attraction is only a particular effect of adhesion. A tube with a small bore, like a hair, is called a capillary tube, from *capilla*, the Latin word for a hair. If the end of such a glass-tube is dipped in water, the water is seen to rise in the tube above the level of the rest of the surface. In a series of tubes of different diameters, the liquid ascends highest in the smallest; or the heights are inversely as the diameters. Water will be seen to rise in a similar way between two glass-plates placed as in the figure, with two of the upright

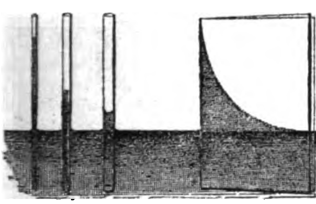

Fig. 2.

edges touching, and the other two slightly apart. The sustained film rises higher as the plates approach, assuming the form of a particular curve. The fluid rises also slightly on the outside of the tubes and plates, and the surface of the sustained column within the tube is seen to be hollow like a cup.

But liquids do not always ascend in narrow tubes or spaces; it is only when they wet the solid substance that they do so. If a greasy glass-tube is dipped in water; or, still better, if a clean glass-tube is dipped in mercury, the liquid inside, instead of rising, sinks below the general level; the surface of the column, too, becomes convex instead of concave.

The rise or the depression depends upon the adjustment between the forces of adhesion and cohesion, as in the case of wetting. When the liquid wets the tube, the particles next its surface have part of their weight taken away or supported by adhesion, and thus a longer column is required to balance the pressure of the rest of the fluid. In cases where the cohesive attraction of the liquid particles within the tube for one another is too strong to permit them to adhere to its surface, that cohesion tends to draw them away from it, and downwards; while the tube prevents them from receiving the support they would have from the liquid particles around them, if it were not there. 'Mathematicians have shewn, that if the adhesion between the solid and the liquid be equal to half the cohesion of the particles of the fluid, the surface at the point of contact will be neither elevated nor depressed; if the adhesion between the two be more than half the cohesion, elevation will occur; and if it be less than half, the surface will be depressed and convex.'

Capillary attraction is exemplified in many familiar appearances, and plays an important part in nature. If a piece of sponge or a lump of sugar be placed so that its lower corner touches the water, the fluid will rise up and wet the whole mass. In the same manner, the wick of a lamp will carry up the oil to supply the flame, though the flame is several inches above the level of the oil. If one end of a towel happens to be left in a basin of water, while the other hangs over below the level of the water, the basin will be emptied of its contents; and, on the same principle, when a dry wedge of wood is driven into the crevice of a rock, and afterwards moistened with water, it will absorb the water, swell, and sometimes split the rock.

A striking illustration of this subject is given thus:—Place a wine or drinking glass on a book on the table, and set another close by it, so as to be on a lower level. Pour some water and some oil into the higher glass; then moisten a piece of cotton-wick in water, and place it so as to form a bridge between the two glasses, with an end reaching near the bottom of each. The water, which was below the oil in the one glass, will in an hour or two be found transferred to the other, leaving the oil behind. If the wick be moistened with oil, the oil will be transferred, leaving the water.

When two light bodies, such as two bits of cork, are left to float on water, near each other, they soon come together, moving at last with a rush. This is sometimes given as an example of the gravitation that draws the planets to the sun; but it is really owing to this attraction of adhesion that we are considering. When the liquid wets the floating bodies, it rises slightly all round them, and this sustained liquid hangs as a weight on them on all sides. So long as it rises equally, there is no motion; but when the bodies come near each other, the space between them becomes like part of the inside of a capillary tube, the water rises higher on the near sides than on the opposite sides, and the bodies move towards the sides that are most strongly pulled. When the floating bodies are not wetted by the liquid, there is a semblance of repulsion between them and it; the surface between the two bodies is depressed, and they are pushed together by the greater repulsion on the outside. If one of two bodies floating on water is smeared with oil, so as to prevent the water from adhering, instead of coming together, the two will recede from each other, for reasons analogous to the above.

Endosmose or *Osmose.*—Connected with capillary attraction is *endosmose*. If two liquids be separated by a piece of ox-bladder, the one below the membrane being pure water, the other above being a solution, say of carbonate of soda, the water will pass through the membrane against gravity, and raise the solution above its former level. A smaller portion of the solution finds its way into the water. This remarkable phenomenon is known as *endosmose* and *exosmose*, or simply as *osmose*. It is not yet fully understood, but is believed to play a part in the passage of the fluids through the membranes of living animals and plants.

Adhesion between two Liquids.—The lower half of a tube may be filled with water, and the top with alcohol

or spirits, with little disturbance at first; but after a time the two liquids will be found equally *diffused*—part of the heavier liquid rising up, and of the lighter being drawn down, by the force of adhesion between the two. Where there is no adhesion between two liquids—as in the case of water and oil—they do not diffuse or mix.

Adhesion between Solids and Gases.—Dry iron filings, and even small needles, when gently laid on the surface of water, will float, though eight times heavier than the water, because each has a film of air adhering to it so strongly, that even when it does sink, it carries a portion of the air along with it. In making barometers, it is found that air adheres so firmly to the surface of the glass, that the mercury must be boiled in the tube before it can be expelled. Some porous solids, such as charcoal, absorb air and other gases to an amount many times their own bulk, the force of adhesion condensing the gases on the surface of their molecules. When a lump of sugar is dropped into a cup of tea, the atmospheres of air which surround the particles do not quit them till they are dissolved; bubbles are seen rising till all the sugar has disappeared.

Chemical attraction is a molecular force, whose effects are of a different kind from those of cohesion. If we divide a piece of marble by breaking it into parts, however small, each part is still marble. But the chemist takes it to pieces in a different way. Out of a piece of marble he will produce three distinct substances, altogether unlike the original body—a metal not unlike silver, a black body called carbon, and a gas resembling air. Most of the substances of which our earth is made up are thus composed of two or more different substances. When the chemist tries still further to analyse, or take to pieces any of the three substances he found in the marble, he finds he cannot; out of the carbon he can make nothing but carbon, and so with the others. When a substance thus resists being divided into other substances, it is said to be a simple substance or *element*. Of these elements there are in all about sixty known; and these combine in unions of two, three, or more, to form most of the bodies that we see around us. Thus, water is composed of two gases like air in appearance; vermilion, of sulphur and quicksilver. Such unions are chemical unions, and the attractive force that produces them is *chemical attraction*. Cohesion and adhesion produce unions, but they leave the united substances with their qualities unchanged; chemical attraction, in uniting two substances, changes their properties, and produces a new substance, with new properties. The investigation of changes that thus alter the constitution of bodies, belongs to the science of CHEMISTRY.

MOTION AND FORCES.

Motion is change of place, and its opposite is rest. Motion in any one body has always reference to the place of other bodies, and various distinctive terms are used indicative of this reference. A man sitting on the deck of a ship has a *common* motion with it; if walking on the deck, he has *relative* motion to the vessel. *Absolute* motion means change of place with respect to space itself. But we have no means of marking a fixed point in space, and therefore can never observe such a motion; we know only relative motions. As little do we know of absolute rest. The earth is in constant rotation and also revolution round the sun; and the sun himself is in motion, we know not whither. Motion, and not rest, is the great law of the universe.

Velocity, or speed of motion, is measured by the space passed over in a given unit of time; as when we say that a man walks three miles an hour; or that sound travels 1120 feet in a second. The velocity is *uniform*, when equal spaces are always passed over in equal times; it is *accelerated*, when gradually increased, and *retarded*, when gradually diminished. If the increase or diminution is equal in equal times, the motion is said to be *uniformly accelerated* or *uniformly retarded*. *Force* is any agency that produces motion in a body; when the body is not free to move, the force exerts a *pressure*. Force and pressure are often used indifferently; and weight being the kind of force with which we are most familiar, the amount of a force or pressure is usually expressed in so much weight; as ounces, pounds.

A body when put in motion acquires the power of setting other bodies in motion: in other words, it acquires force; and this force of a moving body is called its *momentum* or *quantity of motion*. Momentum does not depend upon velocity alone. Of two balls moving at the same rate, but the one having twice the mass of the other, the larger will have just twice the force or momentum. Momentum, then, is made up of velocity and quantity of matter taken together. To get the comparative momenta of two bodies in numbers, we multiply the weight of each by its velocity. If two balls of 6 and 8 pounds move, the first 100, the other 50 yards in a second, the momentum of the first will be to that of the second as 6×100 to 8×50, or as 600 to 400, or as 3 to 2.

LAWS OF MOTION.

The leading truths respecting the movements of bodies have been summed up in the shape of a few axioms, or propositions, which were first put into shape by Newton under the name of *Laws of Motion*. Various modifications of these laws have been proposed, with a view of rendering them more explicit. We shall give them as laid down by Newton, and then follow them up with observations on each.

1*st*, Every body must persevere in its state of rest, or of uniform motion in a straight line, unless it be compelled to change that state by forces impressed upon it.

2*d*, Every change of motion must be proportional to the impressed force, and must be in the direction of that straight line in which the force is impressed.

3*d*, Action must always be equal and contrary to reaction; or the actions of two bodies upon each other, must be equal, and their directions must be opposite.

FIRST LAW.

This law is little else than a definition of the property of Inertia or Inactivity. In fact, all these laws are but expansions of the idea of inertia; the facts they state go to make up that idea, or flow from it as consequences. There are three things to be attended to in this law—namely, the *persistency* of matter, both in rest and motion, when not acted upon by external agency; the *uniform* velocity; and the *straight* direction of motion when once begun and left to itself. The first has been already illustrated under the head of Inertia; and when we say that unobstructed motion is naturally *uniform*, we are only repeating in a different form the same truth. If we cannot conceive a body beginning to move without a cause, neither can we conceive a moving body beginning of itself to move faster; and if we believe that when a body in motion is stopped, something external stops it, we must believe that when its motion becomes slower, something is retarding it.

A little reflection brings out the truth of the third point, namely, that motion is naturally *straight*. If a ball projected forward is seen to bend to the right or the left, we infer at once that something interfered with it. That it bends downwards, we know to be owing to the attraction of the earth. Motion therefore requires force to bend it. It might seem at first sight that a body once set amoving in a circle ought, by the law of persistence, to go on moving in the same path when left to itself. But the *same path* is, in this case, not the *same direction*. A body moving in a circle, or any other curve, is continually changing its direction; it is always turning a corner, as it were.

SECOND LAW.

That every change of motion is proportional to the force that produces it, is involved in the way of measuring force, which is by the quantity of motion it gives or takes away. As to the *direction* of the resulting motion, the law requires careful explanation. It has been proposed to express it in the following terms, as less liable to be misunderstood :—'All force, or cause of motion, in any direction, produces its effect in that direction, and in no other.' When the body is previously at rest, it is self-evident that, if unobstructed, it will follow the direction of the force that begins to act upon it; but if it is already in motion in one direction, and a force then comes to act upon it in another direction, it is not so clear what course it will take. To determine the path or line in which a body will move when thus acted upon by more forces than one, is a problem which lies at the foundation of the whole science of mechanics. It is usually treated under the title of the

Composition and Resolution of Motion.

To avoid confusion on this subject, it is necessary to attend to the difference between moving in the same straight line, and moving in the same direction. The ball B in the figure is moving in the same direction, whether it move in the line AC or in any line parallel to AC, as *gf* or ED; in any of these cases it is equally approaching the line CD. In the same way a motion from B towards E, or from *h* towards *i*, or from C towards D, is still in the same direction, because these lines are parallel.

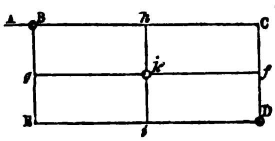

Fig. 3.

Now, let the ball be moving along the line AC with a velocity that would carry it from B to C in two seconds, and when at B let it receive a blow that would carry it from B to E in the same time; the question is, How will the ball now move? This is best understood by supposing it placed not on a plane surface, but in a groove in the upper side of a movable bar lying on a table. The ball being then set arolling at the same rate as before along a groove in the bar AC, let the bar be made at the same time to slide across the table, keeping parallel to itself, and carrying the ball along with it, so as to arrive at the position ED in two seconds. The common motion of the bar and the ball will not in any way interfere with the motion of the ball in the groove, any more than the common motion of a ship and a man on board of it interferes with the man in walking across the deck. The ball will be at the end of the groove at the end of the two seconds, just as if the bar had been at rest; it will therefore, as a result of the two movements, be found at the point D.

If the position of the ball on the table is observed at the intermediate points, it will be found to describe a straight line from B to D; for since we have supposed both motions uniform, the bar will, at the end of the first second, be in the position *gf*, midway between BC and ED, and the ball will at the same instant be halfway from *g* to *f*, at *k*; and it can be proved that *k* is in a straight line between B and D. The same could be shewn as to any intermediate stage.—When both motions are not uniform, the body moves in a curve, as will be seen in speaking of projectiles.

The movable groove is introduced to make the effect of two movements conjoined more readily conceived; to shew palpably, as it were, that a body may be moving in two directions at one and the same time. But if it receive the second impulse by a blow while rolling freely on the table, it will still arrive at D by the same path.

In any case, then, when two forces act upon a body, if we draw two straight lines, AB and AC, in the directions of the two forces, and make the lengths AD and AE in proportion to the velocities that the forces would give to the body if acting separately; then if we draw EF and DF parallel to AD and AE, and join AF, this line, which is called the *diagonal*, gives the direction that the body will move in, and also its velocity; that is, the body acted on by the two forces moves from A to F in the same time in which it would have moved from A to D by the one force alone, or from A to E by the other force alone. A figure thus formed represents both the motions and the forces that produce them, and is called the *parallelogram of forces*. AD and AE are called the *components*, and AF the *resultant*.

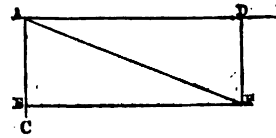

Fig. 4.

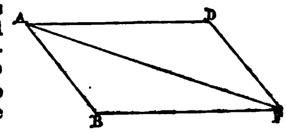

Fig. 5.

In figures 3 and 4, the forces are represented as acting at right angles to one another; but the angle may vary, as in figures 5 and 6, and the learner should observe the effect on the resultants as he draws parallelograms with angles still narrower or still wider.

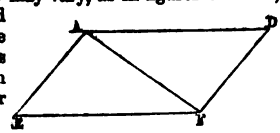

Fig. 6.

We arrive at a similar result if, instead of motions, we consider a set of forces acting against one another so as to prevent motion. When forces thus balance one another, they are said to be in *equilibrium*; and the investigation of such cases forms the part of Mechanics called *Statics* (from a Greek word signifying 'to stand'), while the consideration of force producing motion belongs to *Dynamics* (from the Greek word for 'power').

Two strings fastened to the ring P, and drawn in opposite directions by equal forces, will keep the ring at rest, and the forces are then in equilibrium. The forces A and B, in fig. 7, are represented by two weights, say of six pounds each, suspended over pulleys. Now, it is evident that for one of the two forces we could substitute two other forces, as in fig. 8,

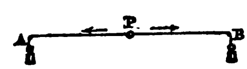

Fig. 7.

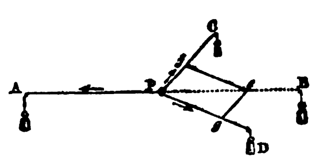

Fig. 8.

pulling in the directions PC, PD, which, if properly adjusted, would still keep the ring at rest. The effect of the two new forces, C and D, is thus equal to the effect of the one force, B, and the force B is said to be *resolved* into the two, C and D.

The exact proportion of the two to each other and to the one original force, may be determined by setting off a length of six parts along P*e*, to represent the six pounds of the original force, and then drawing *ef* and *eg* parallel to PD and PC. We have then a parallelogram of forces. P*f* represents the magnitude of the force C, P*g* that of the force D, and P*e* is the resultant.

As *ge* in the last figure is equal to P*f*, and in the same direction, the two component forces and their resultant are represented by the three sides of the triangle P*ge*; and the resolution of forces is thus often represented by the half of the parallelogram of forces, to save drawing the whole.

The following is an example of the resolution of forces:

Let TP be a ship, SL its sail, WA the direction of the wind, and let the length of WA represent the pressure of the wind on the sail. WA can be resolved into AB perpendicular to the sail, and BW parallel to it, the latter of which has no effect in pressing on the sail; therefore AB is the effective pressure on the sail. Were the vessel round, it would move in the direction BA. Let BA be resolved into CA and BC, the former, CA, acting in the direction of the keel or length of the vessel, or in the direction CA, and the latter perpendicular to it, or in the direction of the breadth. The former pressure, CA, is the only pressure that moves the vessel forward, the other, BC, makes it move sideways. From the form of the vessel, however, this latter force, BC, produces comparatively little lateral motion; any that it does occasion is called *leeway*.—By a similar double resolution, we may represent how much of the actual force of the wind is effective in turning round the arms of a wind-mill.

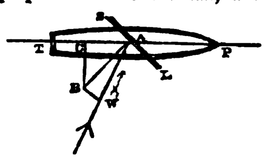

Fig. 9.

THIRD LAW.

When one stone is dashed against another stone at rest, the moving stone is hit as hard, and is as likely to break, as the one at rest; and when one person knocks his head against his neighbour's, it is difficult to say which is most hurt. The hand pressed against a fixed body is equally pressed in its turn. If a man standing in a boat attempt to push off another boat of the same size that is alongside, both boats will recede equally from each other; if he pull the other boat towards him, his own boat advances half-way to meet it. A magnet draws a piece of iron towards it; but the magnet is also drawn towards the iron, as is seen when they are both suspended so as to move freely. In all these cases, we see that the body that we consider as acting upon the other, is itself acted upon in turn, and in the opposite direction: this is what is meant by *reaction*.

In saying that the action and reaction are *equal*, it is meant that the momentum produced or destroyed on both sides is the same. If the magnet and the piece of iron above spoken of are of the same weight, they move to meet each other with equal velocities, for thus only can the momentum be the same in both cases. If the magnet is three times the weight of the piece of iron, the iron must move with three times the velocity of the magnet in order to have equal moving force; and so it is found to do. In the case of the boats, suppose the one in which the man is seated to be ten times the weight of the other, then for every ten feet that the light one moves off, the heavy one will recede one foot. The two will thus have the same momentum; and if each were to strike an object, an equal shock would be given in both cases.

In the last instance, both motions would still be visible. But let a boat of a ton weight be pushed away from the side of a ship of a thousand tons' weight, and then only one seems to move; for while the boat moves off a yard, the ship recedes only the thousandth part of a yard, which it would require minute observation and measurement to render apparent. From this we can pass to the extreme case of a boat pushed off from shore. Where is the evidence of reaction here? We see none, it is true; still, the consideration of the cases already adduced, and of a thousand similar, lead us irresistibly to believe that the shore, if it is free to move, must recede from the boat. But the shore can move only by carrying the earth with it; and considering the vast mass of the earth compared with that of the boat, the space moved over would defy measurement, even if we had any fixed mark to count from. We cannot help believing, then, that when a stone falls—in other words, when the earth draws a stone towards it—the earth is itself drawn, or falls, towards the stone.

COMMON MOTION.

When a system of bodies has, from any cause, received a common motion, their positions, with regard to one another, remain unaffected by it, and in considering their relative motions, we may leave their common motion out of account; everything is as if the system were at rest. This arises from the property of inertia, as already expounded. When a ship is going steadily, all things go on in the cabin as in a room. On deck, a ball thrown upwards comes down in the same spot; the deck has not slipped away from under it. The *motal inertia* of the ball carried it on while in the air with the motion it had acquired from the ship.

The feats of equestrians depend upon this law of common motion. Riding at full speed, they throw up balls, which return into the hand. The rider springs right up from the saddle, and alights on it again without falling behind the horse. When a bar is held in his way above the horse, he does not require to leap forward in surmounting it; he springs directly upwards, and this upward motion, combined with the forward motion he has in common with the horse, results in carrying him in a curve over the obstacle, and planting him on the very spot of the horse's back he sprung from.

All bodies, at any part of the earth's surface, have a common motion eastward along with the earth in its rotation. The velocity of that motion is greatest at the equator, and grows less towards the poles, as the circles described grow less and less. When a current of air, then, or of water in the ocean, is moving from any place in the northern hemisphere towards the equator, it carries the eastward velocity of the place it starts from to places where that velocity is greater; it thus has a tendency to fall behind the surface of the solid earth, which gives it the semblance of being deflected from its direct south course towards the west. (See METEOROLOGY.)

TERRESTRIAL GRAVITY.

It is a law, as we have seen, wide as the universe, that every particle of matter acts upon every other particle by the force known as gravitation, which draws them one towards another. We are now to consider the laws of this force, and explain the more important phenomena it gives rise to.

The attraction of gravitation is always in proportion to the mass of the attracting body. This will be readily admitted. A force is exerted by each atom, and the more atoms the more force. It is not the volume or bulk of the body, but its quantity of matter that decides its effect. Gravitation, again, acts at all distances, but with diminished effect as the distance increases. The decrease, however, does not go on in a simple proportion; twice the distance does not give simply half the attraction. If, at the distance of a foot, the force of attraction were a pound, at the distance of 2 feet, it would be $\frac{1}{4}$ of a pound; at 3 feet, $\frac{1}{9}$ of a pound; at 4 feet, $\frac{1}{16}$ of a pound. This is expressed by saying that attraction varies inversely as the squares of the distances between the bodies.

This law holds with many other influences besides gravitation; with light, for instance, and whatever is diffused from a centre in all directions. By considering fig. 12, we see that the same quantity of light which, at a yard from a candle, is diffused over a board of one foot square, is, at the distance of two yards,

diffused over a board having a side of two feet, but containing four squares of one foot to the side.

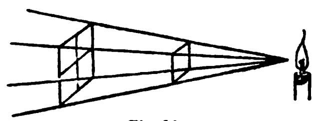

Fig. 10.

The distance between two mutually attracting globes is measured from centre to centre. The attraction of the earth, then, on a body at its surface is exerted at the distance of about 4000 miles, which is the length of its *semi-diameter;* at the height of 4000 miles above the surface, or at the distance of two semi-diameters from the centre, the attraction is reduced to one-fourth. The moon being at the distance of sixty semi-diameters, the earth draws it with a force which is only a 3600th part of what it would be, were the moon at the earth's surface. It belongs to astronomy to treat of gravitation as ruling the planetary motions; we have here to speak of the phenomena it produces on bodies at or near the earth's surface.

The attraction of the earth for bodies on its surface is so strong, owing to its overwhelming mass, that it overpowers their attraction for one another, and renders it in most cases inappreciable. But a plumb-line suspended near a large mountain is sensibly drawn from the perpendicular; and by a delicate instrument, called the torsion-balance, the action of a large ball upon a small one has been measured. The *weight* or gravity of a body is another name for the force with which it is drawn towards the earth.

The force of gravity is directed towards the earth's centre. A plumb-line indicates the direction, and we usually call it *downward;* but *down* and *up* are no fixed directions; they vary for every part of the earth's surface, and what is *down* to us, is *up* to our antipodes. This is shewn in the figure, which represents balls falling towards the earth at three different places on the surface. At points, however, not far distant from one another, downward or vertical lines do not differ sensibly from parallel lines, owing to the great distance of the centre.

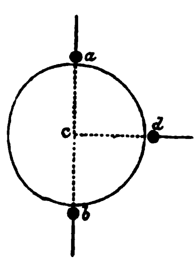

Fig. 11.

Falling Bodies.

Perhaps nothing explains more phenomena than the complete understanding of what takes place when a body falls; for half the motions in the world are caused, directly or indirectly, by falling. Falling is the best instance of a *uniformly accelerated* motion. Gravity not only puts a body in motion, but *continues* to act on it with equal force after it is in motion, and thus is uniformly adding to its speed. This acceleration is seen in every body dropped from a height through the air; and no less in a rock rolling down a declivity, which continually gathers force as it descends, till its momentum is sufficient to shatter itself and everything it encounters to pieces. In a water-fall, the increasing velocity breaks off the lower part of the descending column in drops, which separate more and more as they descend. When a viscid liquid, like molasses, is poured out from a height, the bulky sluggish stream becomes gradually rapid and smaller, and is at last reduced to a thread; but wherever a vessel is held into the stream, it fills equally fast.

All bodies, heavy and light, would fall equally fast, if the resistance of the air were removed. A ball of lead two pounds' weight does not fall faster than a ball of one pound. A gold leaf, however, will fall considerably slower than the same gold in a solid state, because it exposes much more surface to the air. That this is the cause of the difference, is shewn by an experiment with the air-pump, in which a guinea and a feather are dropped in a vacuum, and fall to the bottom together.

It has been well ascertained by observation, that when a body begins to fall from a state of rest, it descends 16 feet 1 inch in the first second of time. Suppose that no fall had ever been observed beyond that point, and that we had to find by reasoning what the body would do during the next second. The first consideration is, How far would the body fall, if gravity were to cease?—in other words, What velocity has it acquired? It would not be unnatural to say 16 feet (we omit the 1 inch), since that is the space it fell in the second that is ended; but reflection shews that this cannot be the case. During the first half of the second, it made very little way, and the greater part of the distance was passed over in the last half; 16 feet expresses the mean velocity, or the velocity it had at the middle of the second, and at the end it must have been moving with a velocity just double the mean. The velocity acquired, then, at the end of the first second is 32 feet; and if gravity were to cease, it would, by the law of inertia, move over 32 feet in the next second. But gravity still acting, will make it fall another 16 feet in addition to the 32, or 48 feet in all; and will create as much velocity in addition as it created in the first second, so that if it were to cease at the end of the second second, the body would move 64 feet in the third second. Thus, during the second second, the body will fall through three spaces of 16 feet, and at the end of it, will have its velocity double of what it was at the end of the first second. The whole space fallen during the two seconds will thus be four spaces of 16 feet.

We arrive at this result by reasoning, and observation proves it correct. Without giving the steps of the investigation for the succeeding spaces of time, the results may be exhibited in the following table:

Number of Seconds.	1	2	3	4	5	&c.
Velocities at the end of number of seconds, in spaces of 16 feet, .	2	4	6	8	10	&c.
Spaces fallen through during each successive second, ...	1	3	5	7	9	&c.
Spaces counted from beginning of fall, ...	1	4	9	16	25	&c.

For example: The third column, headed 3 (seconds), informs us that at the end of 3 seconds a falling body is moving (for the instant) at the rate of 6 spaces of 16 feet—that is, of 96 feet—a second; that during the third second it falls five spaces, or 80 feet; and that the whole distance fallen during all the three seconds is 9 spaces, or 144 feet.

The distances that bodies fall, then, do not increase simply as the times, but as the *squares* of the times. To find, therefore, how far a body will fall in any number of seconds, multiply the number of seconds by itself, and that product by 16. Thus, in 7 seconds, a body will fall $7 \times 7 \times 16 = 784$ feet. The height of a precipice might be roughly measured in this way, by observing how many seconds a stone takes to reach the bottom.

As a body in descending to the earth receives increasing accessions to its velocity during every successive second, so when a body is projected upwards from the surface of the earth, its velocity decreases in the same proportion till it comes to a state of momentary rest, when it instantly begins to descend with a gradually increasing velocity, which at any point in the descent is equal to its velocity at the same point when ascending. In this calculation, however, we omit the influence of the atmosphere.

Projectiles.

Any heavy body launched or *projected* into the air with an impulse, is a projectile; and to investigate the

motions of such bodies forms a distinct branch of the science of motion.

Suppose a cannon-ball fired from the top of a tower, whose height is represented by the line A4′, in the direction of the horizontal line AB. The force of the

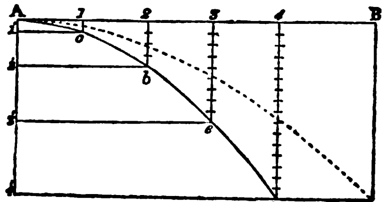

Fig. 12.

gunpowder ceases to act as the ball leaves the cannon, and the ball retains a uniform velocity which would carry it over equal spaces in equal times. Let A1 be the space the ball would describe in a second, if acted on only by the projectile force, and set off a number of equal spaces along AB. Now, from the moment the ball leaves the mouth of the cannon, it is acted on by gravity; and while moving in the direction of AB, also falls; so that at the end of a second it must be 16 feet lower than it would have been if gravity had not acted—that is, if we take the perpendicular line 1*c* to represent 16 feet, the ball will at the end of the first second be at *c*. The horizontal motion being uniform, the ball at the end of the second second would be at 2, or twice as far towards B; but its downward accelerated motion has in the meantime dragged it down through three spaces more—in all four spaces—of 16 feet below the horizontal line. Making 2*b*, therefore, equal to four times 1*c*, gives *b* as the point where the ball will be at the end of the second second. By similar reasoning, if 3*e* is made equal to nine times 1*c*, 4*f* equal to 16 times 1*c*, &c., according to the law of accelerated motion; *c*, *f*, &c., will be the points at which the ball will be found at the end of the third, fourth, &c., seconds. The resultant of these two dissimilar motions, the one uniform, and the other uniformly accelerated, is a curve of the kind called a parabola, as represented in the figure.

From the above investigation, this remarkable consequence follows: that a body projected horizontally from a height above a level plane, comes to the ground as soon as if it were let fall perpendicularly. The ball reaches *f* in the same time that it would fall from A to 4′. A greater velocity of projection would make it take a wider flight; but its horizontal motion does not interfere with its downward motion, and at the end of four seconds it must be at some point in the same horizontal

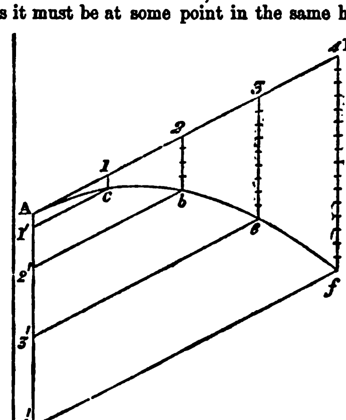

Fig. 13.

line—at *g*, for example. Two balls, then, projected horizontally from the same height above a level plane, though the one may range only a mile, and the other two miles, will reach the ground at the same time.

Projectiles are mostly thrown, not horizontally, but in an oblique direction. We arrive, however, at the path described in the same way as in the last case. AB, in fig. 13, is the line of projection as before, and 1, 2, 3, 4, are the points to which the velocity of the ball would carry it in 1, 2, 3, 4 seconds; while 1*c*, 2*b*, 3*e*, 4*f*, represent the distances which gravity will drag it downward from its original direction in the same times respectively. When the elevation of the direction and the velocity are given, Conic Sections teaches us how to find the distance and time of flight of a projectile, the direction of the ground being also supposed known.

The laws above arrived at respecting projectiles are strictly true, only on the supposition that the movements are made in empty space. But every projectile has to encounter the resistance of the air; and that resistance becomes so great when the velocity is very high, that in the practice of gunnery the theory is of little value. With a small velocity, however, a body thrown through the air describes a path not differing much from a parabola.

Since the distance of the flight, and the width of the curve described by a projectile, increase with its initial velocity, we can conceive the velocity increased until the curve became as large as that of the earth itself. If this were the case, the projectile, instead of falling, would, if the resistance of the air were removed, continue to go round and round the earth for ever. We thus arrive at the idea of planetary motion. The moon, for instance, is constantly falling towards the earth, like a cannon-ball shot horizontally; but the projectile velocity which it had from the beginning, and which, as it moves in empty space, it retains undiminished, is sufficient to carry it clear round in the curve called its orbit.

Centre of Gravity.

The centre of gravity of a body is that point about which the body balances itself in all positions. When a rod of uniform thickness and density is suspended by its middle point, it remains at rest. There is as much matter on the one side as the other; the atoms balance one another in pairs; and it is as if the whole were collected at the point of suspension. The centre of gravity of such a rod is the central point at its middle part; and if the substance of the rod is pierced, and this central point rested on a fine needle, the rod will remain immovable in whatever position it is put.

Whenever bodies are regularly shaped, and of uniform density, their centres of gravity may be found by mathematical measurement, as in the case of the rod. Thus the centre of gravity of a globe is evidently in its middle point, or centre of dimension. In whatever direction a plane is made to pass through the centre, it cuts the sphere into two equal parts, and every particle in the one half has an equal and corresponding particle in the other similarly situated, so as to balance it. Suspend the centre, therefore, and the globe remains at rest, whichever side is uppermost. Similarly, the centre of gravity of a block of wood, whether cubical or oblong, is in its middle point, which is easily found by measurement.

The position of the centre of gravity in a triangular-shaped body is not so obvious. It is thus found. If ABC represent the surface of a thin triangular board, we may suppose it composed of a number of small rods laid side by side, the line AB representing the first, and the others gradually diminishing in length to the top. Now, the centre of gravity of the rod AB is in its middle point D; and if we join the points D and C

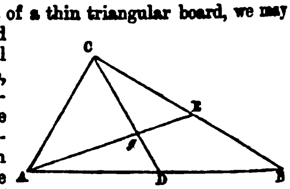

Fig. 14.

the line will pass through the centres of gravity of all the other rods; because it is a property of a line drawn from the top of a triangle to the middle of the opposite side, to bisect or pass through the middle of all lines in the triangle parallel to that side. The centre of gravity of the whole, therefore, must lie somewhere in the line CD. Again, by conceiving the triangle made up of rods parallel to the side CB, and drawing a line from A to the middle point E, we see that the centre of gravity must, in like manner, lie somewhere in the line AE. Now, since it lies also in CD, it can lie only where the two cross—namely, at *g*. We have thus found the centre of gravity of the surface, as it were; and if the board have any sensible thickness, its actual centre of gravity will lie behind *g*, at the distance of half the thickness. It is one of the properties of the triangle, that the line D*g*, determined as above, is always one-third of the whole line DC; thus the centre of gravity of a triangle is readily found.

When two balls are connected by an inflexible rod, they form but one body, and the common centre of gravity is not situated in either, but between them in the rod joining their centres. If the balls are equal in mass, it will evidently be in the middle of the rod; but if they are unequal, the point where they balance each other is found to lie nearer to the larger mass.

The centre of gravity has always a tendency to seek the lowest point, and this enables us readily to find the centre of gravity of an irregular body. For example, let a painter's pallet be suspended from the thumb-hole, as in the figure; we know that the centre of gravity must be perpendicularly below the point of suspension, and if we allow a plumb-line or a straight rod to hang down from that point in front of the pallet, and mark the line under it, the centre of gravity must be on that line. Next, suspend the pallet from any other point, D, and apply the plummet as before, and another line is found also containing the centre of gravity, which must therefore be where the lines cross. If a third line of direction is tried, it will be found to pass through the same point.

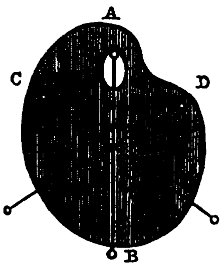

Fig. 15.

A perpendicular line from the centre of gravity, which is called the *line of direction*, must fall within the base of any object resting on the ground, otherwise it will fall. A structure may overhang its base within certain limits. In A (fig. 16) the line of direction falls within the base,

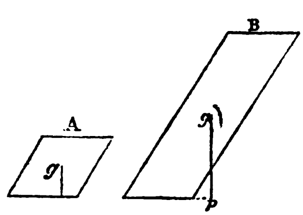

Fig. 16.

so that the centre is still supported, and would have to *rise* before the body could tumble; in B, the centre is unsupported, and moves in a descending curve from the first. The instability here arises from the *height* of the object, for the slope and base are the same in both.

This explains why vehicles when loaded high, or made *top-heavy*, are so easily upset. Figure 17 represents a cart crossing an inclined plane; or we may suppose that one wheel is tilted up in passing over a stone. With a load of stones, the centre of gravity would be about C, and the line of direction falling just under the wheel, the cart would escape being upset, though it might be narrowly. But if the load is such as to throw the centre of gravity into the position C′, the vehicle must fall over.

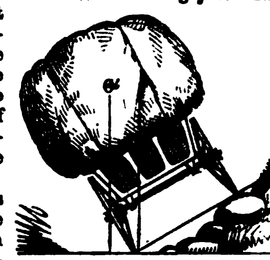

Fig. 17.

When a man stands on both legs, the centre of gravity falls between the feet; and the stability is increased by placing the feet apart. In resting on one foot, the body must be thrown over that foot; hence walking requires that the body be swayed slightly from side to side. In persons of a broad build, this oscillating motion is necessarily greater than in others, and hence the gait called a *waddle*. The walk of the duck is an extreme case of the same thing.

The Pendulum.

Any heavy body, such as a ball, suspended by a string or rod, so as to swing freely, constitutes a pendulum. Swinging is no less an effect of gravity than falling; and from the importance of the pendulum, as a measurer of time, the phenomenon deserves attentive study.

In the accompanying cut, a pendulum of the most common construction is represented. A is the axis or point of suspension; B is the rod; C is the *bob*, consisting of a ball, or a round flattish piece of metal, which is fastened to the rod by a screw behind, and by which screw it can be raised or lowered on the rod; DD′ is the path or arc which the ball traverses in swinging. When the ball is drawn to one side, as to D, gravity urges it downwards, while the tension of the rod draws it towards A. The composition of the two forces makes it describe a descending curve to C, where gravity is completely counteracted by the opposite pull of the rod. But the ball does not stop here; it goes on, by the law of inertia, in the ascending curve CD′, until gravity destroy its acquired motion. If friction and the resistance of the air did not interfere, the ball would reach the same elevation as it started from. But these causes gradually render the ascent less and less, and at last bring the pendulum, when it has no maintaining power, to a state of rest.

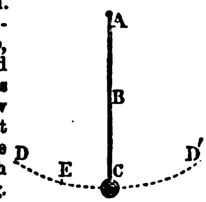

Fig. 18.

One sweep of a pendulum from D to D′ is called an *oscillation*. The size or *amplitude* of the oscillation is measured by the number of degrees in the arc, each degree being a 360th part of the whole circle. For reasons that will appear, pendulums are generally made to describe small arcs, not exceeding 5° or 6°.

The most remarkable property of the oscillations of the pendulum, and that on which its use as a regulator of movement depends, is that, whether long or short, they are all performed in very nearly the same time. If we observe the vibrations of any body set aswinging, we find that though the arc it describes is continually diminishing, there is no sensible shortening of the time in which the single sweeps are accomplished. As the journey becomes less, so does the velocity. Galileo is said to have been the first that distinctly noted and investigated this important fact. The cause is easily seen. The wider the sweep of the ball, the steeper is its descent at the beginning, which gives it a greater velocity, and enables it to go over the longer journey in the same time as over a shorter.

It is only short oscillations that are thus *isochronous*,

as it is called; when the arcs are large, the steepness does not increase in exact proportion to the length, and therefore the isochronism is not perfect. Accordingly, pendulums are made to swing in short arcs; and then, though no contrivance could make the extent of the oscillations exactly uniform, the times are virtually equal.

But though the time of oscillation is not affected by the largeness of the arc, it is by the length of the pendulum itself. Long pendulums vibrate more slowly than short ones. Though the balls B and D in the fig. have the same amplitude of vibration, or go over corresponding arcs, the journey of the one is longer than that of the other. But the steepness of descent, or inclination of the path, is the same in both; therefore B must take longer time to perform its journey than D. We must not, however, conclude that when the length of the arc, or, which is the same thing, of the pendulum, is doubled, the time of oscillation is also doubled. The motion of the pendulum is an accelerated motion; and, as in all other uniformly accelerated motions, the spaces described are as the squares of the times. To give double the time of vibration, then, requires the pendulum to be four times as long; treble the time, nine times as long; and so on.

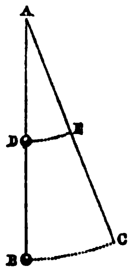

Fig. 19.

The truth of this is easily proved by experiment. Suspend three musket-balls on double threads, as in the figure, so that the lengths measured in the dotted line may be as 1, 4, and 9. While the lowest ball makes one oscillation, the highest will be found to make three, and the middle ball two.

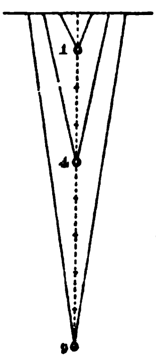

Fig. 20.

A pendulum of a little more than 39 inches beats seconds, and one of one-fourth that length beats half-seconds. As a pendulum that beats seconds must always be of the same length, it forms a fixed standard of measure which can be found again when artificial standards are lost.

When we say that the seconds' pendulum is always of the same length, we must be understood to speak of the same place. In different places, its length varies. At the equator, owing to the shape of the earth, we are thirteen miles further from the centre than at the poles; and therefore the seconds' pendulum must be somewhat shorter at the equator, and grow gradually longer as the latitude increases. The following are the lengths of the seconds' pendulum at a few stations, embracing a considerable range of latitude:—

Spitzbergen,	79° 49′ 58″ N. Lat.,	39·2146 inches.
Edinburgh,	55 58 40 ″	39·1554 ″
London,	51 31 08 ″	39·1390 ″
Jamaica,	17 56 07 ″	39·0350 ″
Sierra Leone,	8 29 28 ″	39·0195 ″

The length of a pendulum is measured from the point of suspension, not to the bottom, or even the centre of the ball, but to a point called the *centre of oscillation*, where the whole mass of the swinging body—rod and ball together—may be supposed concentrated.

We may find pretty nearly the centre of oscillation of a common pendulum, or of any pendulous body, by suspending in front of it, and from the same axis, a small ball of lead attached to a fine thread. This ball and thread form what is called a *simple* pendulum, because the weight of the thread may be reckoned as nothing, and the matter is as nearly as possible in one point. Both bodies are now made to swing, and the thread is lengthened or shortened till the two vibrate in exactly the same time; when they come to rest, the centre of the spot on the pendulous body covered by the ball is the centre of oscillation.

A pendulum alone, without wheel-work, would form a time-keeper, if we took the trouble to observe and count its vibrations, and if friction and the resistance of the air did not, after a time, bring its motion to an end. The use of the wheel-work in a clock is to answer these two ends—to count and record the swings of the pendulum, and to act as a *maintaining power*—that is, to supply to the pendulum fresh motion in place of what is constantly being destroyed. It is still the pendulum that measures the time. A contrivance for bringing the pendulum into connection with the wheel-work, is called an *escapement*, of which there are several varieties. (See Chronology and Horology.)

For adjusting the length of the pendulum, the ball is made to slide on the rod by means of a fine screw. A difference in length of the 1000th part of an inch causes an error of about a second a day. Since all substances are expanded by heat and contracted by cold, changes of temperature must affect the rate of clocks, making them go slower in summer than in winter. *Compensation* pendulums, accordingly, have been contrived, in which expansion in one part is made to counteract expansion in another part. To save space, time-pieces are often regulated by pendulums one-fourth the ordinary length, and therefore beating half-seconds. But a long pendulum, with a heavy bob or ball, is desirable where evenness of rate is the object. A pendulum beating two seconds keeps time much more accurately than one beating single seconds.

CENTRIFUGAL FORCE AND CIRCULAR MOTION.

Motion in a circle, or in any other curve, is something constrained. Free motion is naturally *straight*. This, we have seen, is involved in the idea of inertia. To make a body in motion deviate from the straight line, requires a fresh force in a different direction from the straight line in which it is moving; and if we see a body moving in a circle, which is a constant series of deviations from the straight line, we may conclude there is a constant force acting on it to produce the bending, in addition to the impulse or impulses that urge it onward. Accordingly, when we make a ball whirl round rapidly at the end of a cord, we feel the cord stretched with a sensible force; the ball is pulling outwards, and the hand is pulling inwards. These two opposite pulls must of course be exactly equal, for they are a case of action and reaction. The line of direction of both passes through the centre of the circle, and therefore they are called *central forces*. The outward pull of the ball is called the *centrifugal*, or centre-flying force; the inward pull of the hand, the *centripetal*, or centre-seeking force. The tension of the cord is the measure of both forces.

When a body, constrained to move in a circle, is released from the restraint, what is the result? Suppose the ball B retained by the cord AB, and moving in the direction CEG, &c.; if relieved from the restraint of the cord, it does not fly directly away from the centre, in the line AB prolonged. It has still its onward motion in the direction of the curve, and the only effect of the release from the centripetal force is, that that motion ceases to be bent, and goes on straight in the direction it had at the instant. Now, at any point in a circle, the direction of the curve is that of a straight line drawn through the point at right angles to the diameter. Such a straight line is called a *tangent;* and thus motion in a circle, when released from the constraining force, becomes motion in the tangent, or flies off at a tangent. At C, for instance, the

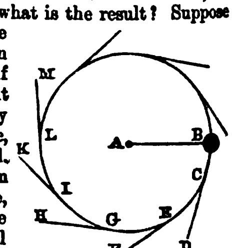

Fig. 21.

direction of the ball, when set free, would be CD; at I it would be IK.

The tendency to fly off from the centre and at a tangent, is exemplified in a multitude of phenomena. A stone let go from a sling is the most familiar instance. In grinding corn, it is the centrifugal tendency that makes the corn find its way from the centre, where it is admitted, gradually towards the circumference, where it escapes as meal. When a vessel with water in it is rapidly turned round like a horizontal wheel, the water recedes from the centre, and rises up round the sides. The potter takes advantage of this in his art: the soft clay is kept rapidly rotating while he is moulding it, and thus it tends of itself to widen out. The same is the case in glass-making, and many other arts.

In equestrian performances in a circus, both rider and horse incline their bodies inwards; they are leaning against a force which is impelling them outwards, and which thus sustains a part of their weight. A skater must do the same in describing a curve. Centrifugal force may be made altogether to counteract gravity: a tumbler of water placed in a sling may, by beginning with short swings, be at last made to go round and round in a vertical circle, where at one part the mouth is downward, without spilling a drop. If a round ball of soft clay be turned rapidly on a spindle, it ceases to be perfectly round in all directions: it bulges out at the middle and shortens in the direction of the spindle. This has happened to our earth; and to a still greater degree to Jupiter and Saturn, which have a more rapid rotation on their axes.

The centrifugal force of a body moving in a circle increases as the mass of the body, and as the square of the velocity. It is calculated that if the rotation of the earth were seventeen times faster than it is, centrifugal force at the equator would be equal to gravity; in other words, all bodies would be completely without weight, and a little increase of velocity would throw them off, to circle round like small satellites.

HEAT.

To account for the appearances presented by matter in its several forms of solid, liquid, and gas, we have seen it necessary (p. 196) to assume that there is a *repulsive* force at work among its molecules, counteracting and modifying the attractive forces. This repulsive force would seem to be identical with heat. Heat expands bodies; it overcomes the cohesion of their particles, converting solids into liquids, and liquids into gases; without it, there would be only one form of matter, the solid, and all life and motion would cease on the earth.

Perhaps no class of natural laws are more interesting in themselves, or more practically important, than the laws of heat. A knowledge of them is of direct application in every art and handicraft, as well as necessary for domestic economy and personal comfort. A full discussion of the subject would require a volume; it is only the most general facts that the limits of this treatise permit to be stated.

EXPANSION.

The greater number of bodies, whether solid, liquid, or gaseous, which are not decomposed by heat, are expanded by it: in other words, occupy a greater space when hot than when cold. Solids expand least, gases most, and liquids—speaking generally—are intermediate between them in expansibility.

To illustrate the expansion of solids, a rod of iron may be taken, and its length and diameter exactly measured at the temperature of the air. If it be now raised to a red heat, it will be found to have suffered an increase in length, and to be too wide to fit an aperture through which it passed before. When allowed to cool to its original temperature, it will exactly recover its previous dimensions.

The expansion of liquids is familiarly illustrated by heating a glass flask filled with any liquid. The liquid rapidly expands, and manifests its expansion by running over. If a bladder three-fourths filled with air is held near a fire, it becomes quite stretched, and may be made to burst, thus illustrating the expansion of gases.

Nearly every solid and liquid has an expansibility peculiar to itself. Among solids, the metals are the most expansible bodies. Zinc expands most, platinum probably least among bodies of the metallic class. Glass, brick, porcelain, marble, and stone, have small expansibilities. If a rod of iron which measures 819 lines in length when as cold as melting ice, is made as hot as boiling water, it is found to measure 820 lines. Between the freezing and boiling points, then, iron increases $\frac{1}{819}$ of its length; for the same increase of heat, glass expands only $\frac{1}{1147}$ of its length.

Among liquids, we find those which are most volatile more expansible than others. Thus spirit of wine is six times more expansible by heat than mercury. Gases, unlike solids and liquids, have not specific expansibilities, but each undergoes almost the same amount of expansion for the addition of the same amount of heat.

When heated from 32° to 212°, water dilates $\frac{1}{23}$ of its volume, mercury $\frac{1}{55}$, and alcohol $\frac{1}{9}$; air or any other gas about $\frac{1}{3}$. An increase of 1° of temperature, therefore, increases a body of air by $\frac{1}{480}$ of its bulk.

Water presents a singular irregularity in its expansions and contractions. If boiling water is taken, and allowed gradually to cool, it follows the general law, and goes on contracting until it is within a few degrees of freezing (at 39°); it then begins to dilate, and continues to do so till it come to 32°, the freezing-point. At the moment of becoming solid, it undergoes a sudden enlargement. It is this enlargement of freezing water that causes it to burst pipes and vessels in which it is confined; it is also the reason that ice is lighter than water, and floats on the surface. Ten cubic inches of ice weigh as much as nine cubic inches of water.

In laying the rails on a railway, and in all structures where metal is used, allowance must be made for the expansion and contraction of the metal by change of temperature. If iron rails were fastened down with their ends in close contact in a cold day, they would, when it became warm, press against one another, and become bent and twisted. Hence, a small space is left between the ends. The practical mechanic avails himself of the law of expansion in putting on the tires or rings of wagon-wheels and iron hoops on vats. Being made a degree too small at first, the tire or hoop is heated to redness, and in this state driven on; it is then cooled with water, when it contracts, and draws the parts of the wheel or vessel together with an irresistible force.

THE THERMOMETER.

The thermometer is an instrument in which *temperature*—that is, *the intensity of heat*—is measured by the amount of expansion it produces. The most convenient substances for the construction of thermometers are found to be mercury and alcohol, or spirit of wine. For ordinary temperatures, mercury is preferable; but when too much heat is withdrawn, it freezes or becomes solid, and therefore, for very low temperatures, alcohol is used, which cannot be congealed by any known cold. The mercury or alcohol is enclosed in a glass tube with a hollow bulb at one end, the other being closed. It is then graduated by first plunging it in melting ice, and marking on the glass, or on an ivory scale attached to it, the point at which the mercury comes to stand. This mark is the *freezing-point* of water, for water freezing and ice melting have the same temperature. The thermometer is next placed in boiling water, when the mercury rises to a certain height, and then continues steady. A second mark is here made, which is the *boiling-point*.

The space between these two points is then divided

into a number of equal parts, called *degrees*, and parts of the same length are set off above and below the boiling and freezing points, as far as required.

In the thermometer used in this country, the space between the freezing and boiling points is divided into 180 equal parts, and we begin counting at 32° below the freezing-point. A cipher is placed there, and it is called the zero or nothing-point of the thermometer. The freezing-point of water thus comes to be marked by the number 32°, and the boiling-point, which is 180° higher, by 212°. Thus, we say that a mixture of salt and snow reduces the thermometer to 0°, that the freezing-point of water is 32°, and that its boiling-point is 212°. In the thermometer chiefly used on the continent, the space between the freezing and boiling points of water is divided into 100 equal parts, and the graduation begins at the freezing-point, which is marked 0°, or zero. According to this thermometer, which is called the centigrade, water freezes at 0°, and boils at 100°.

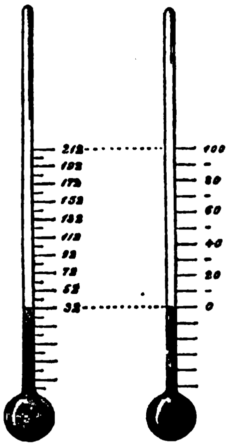

Fig. 22.

The centigrade thermometer is now much employed in scientific researches in this country. To prevent any confusion arising from its being mistaken for the thermometer first described, which is called, from its original maker—who was a Dutchman—Fahrenheit's, or the Fahrenheit thermometer, the letter F is placed after temperatures indicated by his thermometer, and the letter C after those denoted by the centigrade. Thus, water freezes at 32° F., or 0° C.; water boils at 212° F., or 100° C.

From its zero-point each thermometer counts downwards as well as upwards; and to distinguish the degrees below zero from those above it, the former are distinguished by prefixing to them the minus sign —. Thus, mercury is said to freeze at —40° F.; that is, at 40° below Fahrenheit's zero.

Another scale much used in Germany is that called Reaumur's, in which the freezing-point is marked 0°, and the boiling-point 80°. The degrees on this scale are thus larger than those of Fahrenheit, or even of the centigrade: 9° F. = 4° R., or 5° C.; and by means of these proportions, a temperature stated in one scale may be reduced to either of the others, care being taken to allow for Fahrenheit's scale commencing, not at the freezing-point, as the others do, but 32° below it.

Examples of converting degrees of one scale into those of another:

$$20^\circ \text{ C.} = \frac{20 \times 9}{5} + 32 = 68^\circ \text{ F.}$$

$$20^\circ \text{ R.} = \frac{20 \times 9}{4} + 32 = 77^\circ \text{ F.}$$

$$68^\circ \text{ F.} = \frac{(68 - 32) \times 5}{9} = 20^\circ \text{ C.}$$

$$77^\circ \text{ F.} = \frac{(77 - 32) \times 4}{9} = 20^\circ \text{ R.}$$

Fahrenheit chose the temperature of 32° below freezing as the zero-point of his scale, because it was the lowest that had then been observed, and was considered to indicate the complete absence of heat; but it is now known that there are natural temperatures at least 90° below this; and by artificial mixtures, a cold has been produced of —146° F. This last temperature is said to reduce alcohol to the consistency of melting wax, indicating that it is near its freezing-point.

SPECIFIC HEAT.

Different substances require different quantities of heat to raise them to the same temperature. This is expressed by saying that each possesses a *specific capacity* for heat, or, more shortly, a *specific heat*. The fact can be proved in a variety of ways. Thus, if we cause equal quantities of bodies which have all been raised to the same temperature, to melt ice, we shall find that a much greater weight of it will be melted by one body than by another. Thus, mercury at 212° will melt much less ice than an equal quantity of water at the same temperature will, for the mercury has much less heat to give out, so as to produce liquefaction, than the water has.

Specific heats are generally stated with reference to equal weights, rather than to equal measures, of bodies. Thus, a pound of water in rising to a given temperature, absorbs thirty times more heat than a pound of mercury in rising to the same temperature; so that the capacity of water for heat exceeds that of mercury thirty times; and if we call the specific heat of mercury 1, that of water will be 30.

The great specific heat of water has a most important relation to the welfare of the living creatures on the globe. The sea, and other great beds of water, which spread over so large a portion of the earth, cannot in the hot seasons of the year become rapidly raised in temperature; in the cold seasons of the year, on the other hand, they cool slowly, and, moreover, in cooling, evolve much heat, which equalises the temperature of the air as well as that of the land.

The specific heat of bodies is diminished by compressing them or making them more dense. By compressing a portion of air in a syringe, its capacity for heat may be so diminished that the quantity it previously contained, which only raised it to the ordinary temperature, is sufficient, after compression, to make it so hot as to set fire to a piece of amadou, or German tinder. On the other hand, when air is dilated by removing pressure from it, as in the receiver of an air-pump, or in the upper regions of the atmosphere, its capacity for heat is increased, and its temperature falls, the same amount of heat no longer sufficing to warm it to the same degree.

PROPAGATION OF HEAT.

Heat is transferred from one portion of matter to another in three different ways, which are termed conduction, convection, and radiation. *Conduction* implies the passage of heat from one particle of matter to another in physical contact with it. *Convection* is the conveying or carrying of heat by particles of matter raised in temperature, and set in motion. *Radiation* is the emission of heat by a body such, for example, as a mass of red-hot iron at rest, and not in physical contact with the substances to which it communicates heat. The name has reference to the supposition that the heat passes in radii, or rays, like those of sunlight, which can find their way even through a vacuum, and do not appear to require the assistance of ponderable matter to determine their transference.

Conduction.

Conduction is best seen in solids, and particularly in metals, which are the best conductors. A rod of iron placed with one extremity in the fire speedily becomes hot at the opposite extremity, owing to the conduction of heat from particle to particle along the rod. Dense bodies are generally the best conductors; light and porous ones the worst. Feathers, down, fur, flannel, and most of the fabrics used for winter dresses, owe their so-called warmth to their low-conducting power for heat. Their action is altogether negative, being limited to the prevention of the rapid escape of heat generated

by the living beings whose bodies they cover. Hence the best way to preserve ice, is to wrap it in flannel, or other so-called warm covering; for the same means that retard the escape of heat from the living body, retard the access of heat from the air and surrounding objects to the ice.

If the conducting power of gold is expressed by 100, that of copper is 90, of iron 37, of lead 18, of marble 2·3, of porcelain 1·2, of brick earth 1·1. Vessels of porcelain and glass are liable to crack when hot water is suddenly poured into them, because these substances conduct heat slowly, and thus the part first touched by the water becomes expanded, while the parts adjoining are yet cold and unexpanded.

Liquids and gases are very bad conductors of heat, although, from the rapidity with which they rise in temperature, when heat is applied to them, they appear to be among the best conductors.

Convection.

Liquids and gases rise in temperature chiefly in consequence of the convection, not the conduction of heat by their particles. If a spirit-lamp is applied to the top of a tube filled with water, as represented in fig. 23, the upper portion of the liquid is soon heated to boiling, while hours will elapse before even a slight degree of heat will reach any distance down the column. But if the lamp is applied at the bottom of the tube, the heat is soon felt at the top, and the whole liquid is made to boil in a few minutes.

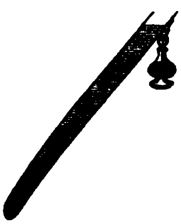

Fig. 23.

This remarkable difference is owing, not to any greater readiness that heat itself has to ascend than descend, for a rod of iron heats equally downwards and upwards, but to a motion that takes place among the particles of the liquid. If a pretty large glass flask be taken (fig. 24), and a few fragments of solid blue *litmus** dropped into it, after it has been filled nearly full of water, on applying heat by a small lamp to the bottom of the vessel, a central current of water, rendered distinctly visible by the blue colour it has acquired from the litmus, is seen to ascend till it reaches the surface of the liquid, when it bends over in every direction like the foliage of a palm-tree, and forms a number of descending currents. The currents which are thus occasioned by heating a liquid are determined by the fact, that when any portion of liquid is warmed, it expands, and has, in consequence, its specific gravity lessened.

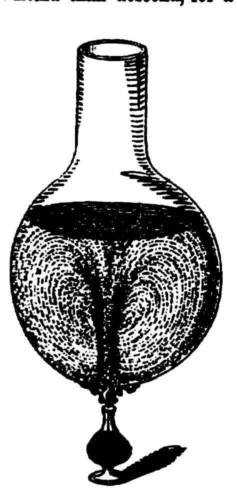

Fig. 24.

Air and other gases are raised in temperature in the same way that liquids are. They conduct heat with extreme slowness, as may be proved by applying heat to the top of an air-tight glass vessel with a thermometer suspended a little below the heated portion. But when the heat is applied from below, currents of circulation immediately begin, as in the case of a liquid. It is a popular belief that a large fire in the open air makes the wind rise; and so far it is quite true. The fire can only be maintained by constant lateral and descending streams of cold air to supply the place of the ascending column. When Moscow was burned, the wind rose so high, that men and horses could with difficulty keep their feet whilst passing through the burning streets.

Our sensations lead us into many errors regarding the temperature of bodies, which attention to their different conducting and conveying powers enables us to correct. Thus, of the several articles in the same room, the table feels colder than the cloth that covers it, and a marble slab colder than the table. They are, in fact, all of the same temperature—the temperature, namely, of the air in the room; but the marble being the best conductor, robs the hand most quickly of its heat.

The cooling effect of a liquid or fluid is much increased by motion, as when the hand is moved through cold water, thus bringing fresh unwarmed portions in contact with it in rapid succession. It is on this last principle that a degree of cold may be borne with a calm atmosphere, which becomes quite killing with even a moderate wind. When air is confined and prevented from circulating, it forms a non-conductor and a warm protection. Hence the effect of double-windows, and of plaster put on laths, so as to enclose a plate of air between it and the wall, instead of being laid on the wall itself. Woolly coverings and furs imprison the air within their substance, and prevent it from circulating, while they afford but few points of solid contact for the direct conduction of heat. These two circumstances combined, give them their remarkable power in arresting the escape of heat; and that power is greater the finer and lighter their texture. Swans' down is said to be the most perfect insulator of heat. From the same causes, snow is an excellent non-conductor, and, like a fleece of wool, protects the earth from any cold much below 32°.

Radiation.

Every hot body in the act of cooling, besides losing heat by the conductive and convective action of the solids and fluids in its neighbourhood, parts with much heat by radiation. Rays of heat pass away from the hot body till it has reached the temperature of the air or surrounding medium. In proof of this, it is only necessary to hang a hot body in the vacuum of the air-pump, when it rapidly cools, although it does not lose heat by either conduction or convection.

The rate of cooling of a hot solid body, so far as radiation is concerned, is remarkably influenced by the state of its surface, and in the case of liquids and gases by the state of the surface of the vessels containing them. Thus, hot water placed in a tin vessel coated externally with lampblack, cools twice as fast as it does in a bright tin vessel. Similarly, if two metallic vessels be taken, the one left bright, and the other covered with linen, hot water will be found to cool much faster in the covered than in the naked vessel. From these observations, it appears that a kettle covered with soot is much less suited for retaining water warm, than if it had a polished metallic surface. So, also, bright metallic covers are the best at table, and metallic tea-pots and coffee-pots are preferable to those of porcelain and stoneware.

Absorption and reflection of rays of heat.—Rays of heat follow almost the same laws as to reflection, absorption, refraction, &c., as rays of light (see OPTICS). When they fall on the surface of a body, they either enter it or are *reflected*. Those, again, that enter are either *transmitted*, like light through glass, or are retained and *absorbed*. It is only the rays that are absorbed that warm the body; those that are reflected off, as well as those that are transmitted, produce no effect on the temperature.

Surfaces that radiate heat best, are found also to imbibe it most readily. If a table, then, is formed of substances according to their power of radiating heat,

* A colouring-matter prepared from certain lichens, and readily procured from any druggist, or dealer in dye-stuffs.

the same table will serve for their power of absorption. The following is such a table, the radiating and absorbing power of a surface of lampblack being expressed by 100:

Lampblack,	100	Tin,	14
White-lead,	100	Brass, polished,	7
Writing-paper,	98	Copper,	7
Glass,	90	Gold,	3
Polished Iron,	23	Silver,	3
Mercury,	23		

Since all the rays not absorbed by a surface must be reflected, this table, read from the bottom upwards, will give the same surfaces in the order of their reflecting powers. It thus appears that the best protection for the head from the burning rays of the sun is a polished metal helmet.

All bodies, even the coldest, are constantly radiating off more or less heat, according to their temperature; all are therefore both giving and receiving rays; but the warmer give more than they receive, the colder receive more than they give. A surface presented towards the open sky, with nothing to radiate or throw back the rays it is emitting, soon becomes cold; but the slightest curtain, such as a net, hung up before it, sensibly arrests the dissipation of heat. It is in this way that clouds act as warm curtains to the earth, and often prevent frosts in spring and autumn nights. The different radiating powers of bodies explains why dew is sooner deposited on some substances than on others. Those that are good radiators lose their heat most quickly, and thus condense the vapour of the atmosphere.

Transmission of Thermal Rays.—Some substances, it has been observed, allow heat to pass through them, as light passes through glass; such substances are called *diathermanous*. Bodies are not diathermanous and transparent in the same degree; for black glass transmits heat well, and water, which is highly transparent, is the least diathermanous of liquids. Of solid bodies, rock-salt is the most diathermanous, alum the least so. Air is a highly diathermanous body. The heat of the sun, in radiating towards the earth, passes through the atmosphere without raising it in temperature, except to a very small extent. In consequence of this, the higher regions of the atmosphere, though nearer the sun, are much colder than the lower, which are raised in temperature by the transference to them of heat from the warm earth.

LATENT HEAT.

The word fluid includes two species—*liquid* fluids or liquids, and *elastic* fluids, or gases. Each of these conditions, liquidity and gaseity, is determined by a very remarkable addition of heat to the solid which it converts into a liquid, and to the liquid which it converts into a gas. The subject, therefore, divides itself into two sections—heat of liquidity, and heat of gaseity.

Heat of Liquidity.

When a solid body, such as ice, is watched whilst melting, a large quantity of heat is observed to enter it without raising its temperature in the slightest degree. This heat which enters the body serves only to melt or liquefy it, without rendering the liquid the least hotter than the solid was which yielded it. The water which flows from the melting ice is no warmer than the ice. The heat which thus renders a body liquid without warming it, is called *latent* or *insensible* heat, because it does not affect our sensations, and does not raise the thermometer. The fact of heat becoming latent, is most decisively demonstrated by mixing a certain quantity—say an ounce by weight—of ice, or still better, from its state of division, of snow at 32°, with an ounce of water at 172°. The result will be found to be, that the snow is all melted, and two ounces of water are procured at the temperature of 32°. The hot water in cooling from 172° to 32°, has lost 140° of heat, which changes the snow into water, but does not raise its temperature above that originally possessed by the snow.

What we have illustrated here with ice, holds good for all solids. Each one of them renders latent a certain quantity of heat in becoming liquid, and retains that heat so long as it remains liquid; when the liquid solidifies, it is again given up. Thus, when water freezes, the 140° of latent heat all abandon it, and manifest themselves as sensible heat. It is this necessity of absorbing such a quantity of heat, and getting rid of it again, that makes the processes of thawing and freezing go on so slowly. The heat developed in slaking lime, is the latent heat of fluidity becoming sensible. Water poured on burnt limestones does not *wet* them; it combines with them, and becomes a solid, and thus gives out its heat of fluidity.

Latent Heat of Gaseity—Vaporisation.

In boiling off a pound of water, or converting it into vapour, it can be shewn by experiment that as much heat is absorbed as would have raised its temperature about 1000°, if it had not gone off in steam. Yet the water rises no higher than 212°, however hot the fire is, and the steam is of the very same temperature as the water it rises from. Thus 1000° have disappeared or become latent in the steam; and before the steam can be condensed into water again, all this heat must be given out. (See STEAM-ENGINE.)

The same is true of the vapour that rises slowly and silently from water at temperatures below boiling (see METEOROLOGY). This absorption of latent heat is the cause of the cold which always accompanies evaporation. By placing water in a shallow vessel under the receiver of an air-pump, and withdrawing the vapour as fast as it rises, evaporation may be made to go on so rapidly that the water becomes frozen.

Sources of Heat.

Next to the sun (see ASTRONOMY), chemical combinations are the chief sources of heat. When two substances unite chemically, their temperature is almost always raised. When the heat is evolved so rapidly as to render the substances luminous—which most substances become when heated to a certain degree—the process is called *combustion* (see CHEMISTRY). *Fire* is a solid rendered luminous or incandescent by combustion; *flame* is gas at a white heat. In ordinary combustion one of the combining bodies is the oxygen of the atmosphere, which is called the *supporter* of combustion; the body with which the oxygen unites is the *combustible*. Most combustible substances are composed chiefly of two elements—carbon and hydrogen, for both of which oxygen has a strong affinity.

Animal heat has the same source as the heat of a fire or of a candle; it arises from a species of combustion. The oxygen taken into the body by the lungs, unites with the carbon and hydrogen of the waste parts of the blood and solids, and converts them into carbonic acid and vapour of water—burns them, in short, and thus produces heat. The average temperature of the human body is 98°·6; and it varies but little with race, climate, or state of health. The other mammalia have almost the same temperature as man; but that of birds is about 10° higher. The temperature of amphibia, fishes, &c., varies but little from the surrounding medium.

Heat can also be produced by mechanical means, such as compression, percussion, and friction. A piece of iron may be rendered hot by hammering; and axles of carriages often ignite from friction. It is found that the amount of heat thus produced is always in proportion to the force expended in the process.

MECHANICS—MACHINERY.

THE application of the laws of motion and forces to objects in nature, or contrivances in the arts, constitutes the branch of Natural Philosophy usually treated under the head MECHANICS, MECHANICAL POWERS, or ELEMENTS OF MACHINERY.

GENERAL DEFINITIONS.

The original signification of the word *machine*—which is the root of the various terms *mechanic*, *mechanical*, and so forth—was art, contrivance, ingenuity, or, in general, the means of bringing about an effect; hence a machine, in its widest acceptation, is an engine or instrument devised to produce an effect. The term *mechanical action* is applied to the action of forces that produce no change in the constitution of bodies, and is therefore distinguished from *chemical*, *vital*, or any other species of action. For example, the pounding of a piece of limestone to powder is strictly mechanical, whether it be effected by the blows of a hammer, or by the silent agency of running water; but the reduction of limestone to a similar state by sulphuric acid, is chemical. In the former case, all the elements of the original limestone remain in the powder; whereas in the latter, it is converted by the action of the acid into a very different compound.

In natural philosophy, machines are usually distinguished as *simple* or *complex*. A simple machine is equivalent to a tool or instrument, as a spade or lever; a complex machine is an engine in which different parts, or various tools, combine to produce the required effect. In ordinary language, these distinctions are not very minutely attended to, though indispensable to the precision of science. *Mechanics* is the term commonly employed to comprehend the science which treats of machines, whether theoretically of their powers, or practically of their application and construction.

Machines are, under all denominations or circumstances, only instruments through which power may be made to act. They only convey, regulate, or distribute the force or power which is communicated to them from some source of motion, and never create or generate power. But although a machine does not create power, or give more power than it has received, it practically applies the power which has been communicated to it in so convenient and easy a manner, that a result ensues almost as surprising as if it had actually generated the whole or a portion of the power it exhibits.

The main purpose in mechanical operations is to overcome, oppose, or sustain a certain resistance or force. This purpose is obtained by applying another species of force. According to the usual phraseology, the resistance or force to be overcome is termed the *weight*, and the force which is applied, the *power*.

The application of force by the human hands, without the aid of instruments or machines, is very limited. In almost all our operations of art, it is found necessary to call in the aid of instruments or machines of some kind. All the instruments which mankind have adopted for their use—from the piece of stick with which the savage scratches the ground as a plough, to the most elegantly finished piece of mechanism—act upon certain fixed principles in nature, which a long course of experience and scientific investigation has developed.

The mechanical powers which exhibit the working of these principles are strictly only three in number—namely, 1. The *Lever*; 2. The *Pulley*; and 3. The *Inclined Plane*. These may be called the Primary Mechanical Powers; and from two of them, the Lever and Inclined Plane, other three are formed, as follows:—1. *Wheel* and *Axle*, from the *Lever*; 2. *Wedge*, from the *Inclined Plane*; 3. *Screw*, from the *Inclined Plane*. These may be called the Secondary Mechanical Powers. The six altogether form the most usually occurring elements of complex machinery.

THE LEVER.

When a box, or other heavy body, is lifted in the hands, the power is applied to the weight directly; it acts without the intervention of machinery. But when a bar is used, as represented in the figure, resting on a support F, we have an instance of a machine interposed

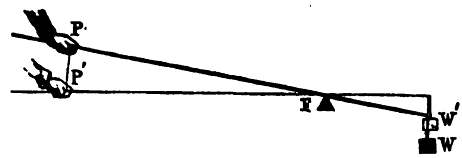

Fig. 1.

between the power and the weight. The effect of this machine is to modify the power in more ways than one. When the hand lifts the weight directly, it pulls upwards at the same point and with exactly the same force with which the weight pulls downwards. But with the machine the hand pushes or pulls downwards as well as the weight, and one effect of the solidity of the rod and of the fixed prop is to convert the downward force at P into an upward force at the other end. And not only this, but when the prop is nearer to the weight than to the power, the power seems to be increased; a downward pressure of one pound at P, causes an upward pull of, it may be, two or more pounds at W.

A rod or bar used in this way is called a *lever*, from the French word for 'to raise.' The point of support is called the *fulcrum*, and the distances from the fulcrum to the points of the lever where the *power* and the *weight* act, are called the *arms* of the lever. The lever is the most important of the simple machines, or mechanical powers, and, in its various modifications, enters most extensively into the composition of complex machinery. The law by which it acts, therefore, deserves attentive consideration. To comprehend thoroughly the nature of the *advantage* conferred by the lever, is to comprehend the fundamental principle of all mechanics.

In treating of the *theory* of the mechanical powers, certain assumptions are made. Thus the object of the lever is to *move* the weight; but the question really examined in the theory of the lever, is not what power is necessary to move a certain weight, but what power is necessary to balance it; what force at P will just keep W at rest, or suspended, if unsupported below. The subject is thus considered as belonging to Statics, or the doctrine of forces in equilibrium. It is obvious that when P and W once balance one another, the least additional force to P will suffice to begin motion. Again, it is assumed that machines are themselves without weight; that the rod or lever, for instance, is a mere rigid line. This is done for simplicity; in practice, the weight of the bar itself has an effect on the resistance, and must be allowed for. Another assumption is, that machines move without friction. A certain amount of force is always necessary to turn the lever about its axis or point of support; but this we do not take into the account. The amount of power consumed in overcoming friction, and the means of diminishing it, are questions for practical mechanics.

Law of the Lever.—When the fulcrum of a lever is placed as in the annexed figure, so that one of the arms, FA, is double the other, FB, it is found by experience that a weight of one pound at P will balance a weight of two pounds at W. And if the arms are in any other proportion—if, for example, AF were made seven feet long, while FB were only two feet; then two pounds at P would balance seven pounds at W. In general, *the power and the weight are to one another inversely as their distances from the fulcrum.*

Fig. 2.

It looks at first sight like magic that a weight of one pound should be made equal in effect to one of two pounds. It seems as if the lever gave us the means of multiplying force to any amount; as if the strength of a boy might be put on a footing with that of a man. It is necessary to get over this false impression. There is no creation or multiplication of force in the lever, or in any other machine, as will appear from the following considerations. If we suppose the power slightly increased beyond what is necessary to balance the weight, it will begin to descend; but in descending six inches, for example, it will raise W only three inches, as represented in fig. 1. What is thus gained in one way, is lost in another; if we make a small force raise a great weight, the force must be exerted through a proportionally great space. One pound will lift ten pounds; but to lift the ten pounds through one foot it must descend ten feet. The two weights, when thus in motion, have equal momenta; the power multiplied into its velocity, is equal to the weight multiplied into its velocity. Since the velocities are in proportion to the distances from the centre of motion, this is the same as to say, the power multiplied into the length of its arm, is equal to the weight multiplied by its arm.

The comparative spaces through which P and W would move in the first instant of time if their equilibrium were disturbed, are called their *virtual* velocities; and the principle that when P and W balance each other, P multiplied by its virtual velocity is equal to W multiplied by its virtual velocity, is called the Golden Rule of Mechanics, and is true not only of the lever, but of all the other simple machines.

When the lever seems to multiply the power, it only accumulates or concentrates it. Suppose that a bale of goods of six hundredweights has to be raised to a platform a yard high, by a man who can lift only one hundredweight. If the bale can be taken to pieces, he may raise it by six lifts of a hundredweight each; but if it is impossible or inconvenient to divide it, he has recourse to a machine to accumulate his strength. By means of a lever with one arm six times the length of the other, he can raise the bale by a pull or a push of one hundredweight; but as the weight rises one yard, the long arm where the man's force acts must move over six yards. He thus makes six exertions of a yard each, exactly as if he lifted the bale in pieces; so that there is no actual saving of force. The lever acts like the milldam, that by treasuring up the flow of a small stream for twelve hours, gives it power to drive the wheel for one hour.

The above explanation of the principle of the lever rests on the notion of equal momenta and of the inertia of matter. The following demonstration is derived from the resolution of forces, and is more mathematical in its nature.

It may be assumed that equal weights, P and P′, suspended at equal arms, CA and CB, of a lever, must balance each other, for there is no reason why the rod should move in one direction more than in another. Also, if the two arms make an angle, as AC, CD, forming a bent lever, turning on the centre C, and if the equal weights, P and P″, both act still at right angles to their respective arms, there is no reason why the system should move; both forces have the same tendency to turn the system about the centre. Suppose such a bent lever, ACD, in

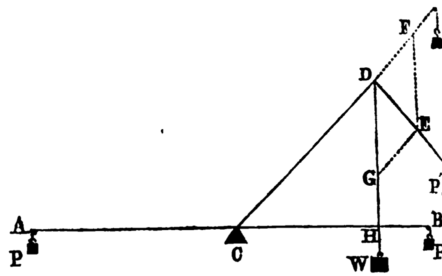

Fig. 3.

equilibrium (the weight P′ being removed), and then let the force P″ be decomposed into two other forces, thus: Prolong CD in the direction of F, draw DH perpendicular to AB, take the line DE to represent the amount of the force P″, and draw EG and EF parallel to CD and DH respectively. In this parallelogram (see Natural Philosophy), DF and DG represent two forces equivalent to the one force DE, and which may be substituted for it. But one of them, namely DF, has no tendency to turn the system round; it merely produces a pressure against the fixed centre, and may therefore be disregarded. There remains, therefore, the force DG (represented by the weight W), which has the same effect in turning the system round as P″ had. Moreover, when a force acts in the direction of any line, it is indifferent at what point of that line it is applied; the equilibrium of the system, therefore, will not be disturbed if the weight W, instead of being attached at D, be attached at H. Now, W being to P″ as the line DG to DE; and since the triangle GDE is similar to the triangle DCH, DG being to DE as DC to CH, it follows that W is to P″ or P, as DC to CH, or as AC to CH; that is, the weight is to the power as the arm of the power is to the arm of the weight. From this it follows, by the well-known property of proportion, that the weight multiplied by its distance from the fulcrum, is equal to the power multiplied by its distance.

This furnishes an easy rule for finding what force is necessary to move a given weight, with a given length of lever; or what weight a given force will move.

Example 1.—Suppose a log of wood, weighing a ton, or 2240 pounds, has to be raised by a lever whose arms are 20 feet and 3 feet respectively, what force must act on the longer arm? Here the product on the one side is $2240 \times 3 = 6720$; what number multiplied by 20 will produce the same product? This is found by dividing 6720 by 20. The quotient 336 is the number of pounds at the long arm, that will balance 2240 pounds at the short one.

Example 2.—A boy, using a pole as a lever, presses on the long arm, which is 15 feet, with a weight of 50 pounds; what weight will he be able to raise at the end of the short arm, which is 2 feet long? The product on the side of the power is 750; and 750 divided by 2 gives 375 pounds as the weight that can be raised.

Example 3.—Two boys, the one 80 pounds and the other 60 pounds' weight, are playing at see-saw with a beam 28 feet long; what point of the beam must rest on the support? The beam must evidently be divided by the fulcrum in proportion to the weights, that is as 80 to 60, or as 8 to 6; which is done thus: $8 + 6 : 8 : : 28 : \frac{28 \times 8}{14} = 16$ feet, the long arm. The short arm is therefore $28 - 16 = 12$. The products on both sides will be found equal; $16 \times 60 = 960$, and $12 \times 80 = 960$.

The power does not necessarily act at the long arm of the lever. The larger weight W (fig. 2) may be

used to raise the less P, as well as P to raise W. When the power acts at the short arm, it requires, of course, to be greater in amount than the resistance it has to overcome; but a small motion of the power in this case makes the weight move over a great space; what is lost in power is gained in velocity. This is often as great an object as an increase of power.

As yet we have represented the prop or fulcrum as situated between the power and the weight. This constitutes a *lever of the first kind*, as in fig. 4. But the power

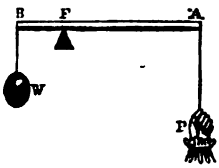

Fig. 4.

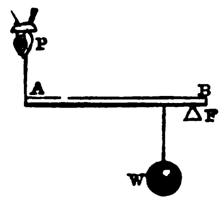

Fig. 5.

and weight may be both on the same side of the fulcrum. In this case, when the weight is between the power and fulcrum, as in fig. 5, the lever is *of the second kind;* and when the power is between the weight and fulcrum, as in fig. 6, it is a lever *of the third kind.*

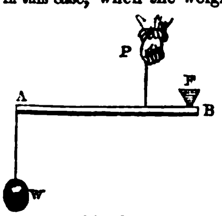

Fig. 6.

These different arrangements make no alteration in the principles already laid down. The effect of each of the forces, P and W, is still measured by its distance from the fulcrum. This distance forms its *leverage* or advantage; and the greater the leverage of either force, so much less does it require to be to balance the other.

The following are examples of implements which act, more or less, on the principle of the lever, beginning with the lever of the first kind.

When the common spade is used in delving, the blade is first forced into the soil by the foot, the handle is then pressed back, the edge of the undelved ground becomes a fulcrum, and the lever-power of the long handle enables a moderate pressure to dislodge the earth from its place. Fig. 7 represents an equally familiar example—namely,

Fig. 7.

a wood-sawyer or carpenter moving a log of timber from its place, by means of a long pole or beam of wood. Stone-masons use a lever of iron of this description, called a crow-bar.

The power of the first kind of lever is frequently seen to operate in machines or instruments having two arms. The most common examples of this nature are pincers, scissors, and similar instruments.

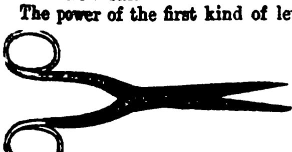

Fig. 8.

In the pair of scissors here represented, the two limbs are seen to be joined together by a rivet at the centre, which becomes the fulcrum of both.

A common scale-beam for weighing is an example of the first kind of lever, formed with two arms of equal length.

There is another kind of balance, called a *steelyard*, which consists of a lever with arms of unequal length, and acts upon the principle of distance from the fulcrum on the long arm compensating for weight on the short arm, as already defined. Fig. 9 is a representation of the steelyard balance. C is the fulcrum or pivot on which the beam is suspended, and freely plays as on an axis; A is the short arm, and the opposite end is the long arm; W is the scale for the reception of the article to be weighed. On the long arm a number of divisions are set off, marked 1, 2, 3, &c.; C1 being equal to CA, C2 equal to twice CA, &c. P is a weight of a certain

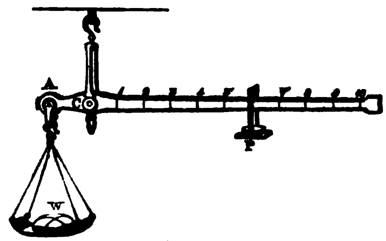

Fig. 9.

heaviness, and being movable by a ring, it can be slipped along the bar to any required point. The same weight is always used, which constitutes one of the principal conveniences of this kind of balance. In proportion as the article to be weighed in the scale W is heavy, so is the weight P slipped along to a greater distance from the fulcrum; and when it is brought to a point where it balances the article, the figure on the bar at that point indicates the amount of the weight. If P be one pound, and if, when suspended from the division at 6, it balance the weight at W, it is evident that the weight will be six times P, or six pounds. And so on with all the other divisions.

The steelyard, though not so ancient as the common balance, is of considerable antiquity. It was used by the Romans, and has long been in use among the Chinese. Neither the common balance nor the steelyard is suitable for shewing the varying weight or heaviness of an article at different latitudes of the earth's surface, because the weights employed are equally affected by the attraction of gravitation and centrifugal force, as the article to be weighed. For this purpose a balance formed of a spring of elastic metal is used.

Examples of the second kind of lever-power are also common. One of the most familiar is that of a man pushing or lifting forward a bale of goods, as represented in fig. 10, in which the bale or weight W presses against the lever between the power P and the fulcrum F.

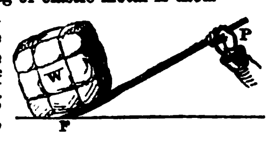

Fig. 10.

Another example of this lever is that of a man using a wheel-barrow, as represented in fig. 11. The axle of the wheel is the fulcrum; the body of the barrow, with its load, is the weight; and the two handles form the lever, the man's muscular strength being the power, and acting at the extremity, while the weight is situated between the extremity and the fulcrum. In proportion as the man shortens or lengthens the handles

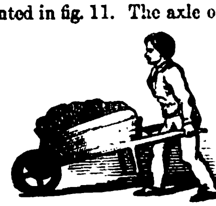

Fig. 11.

in holding them, so does he increase or diminish the weight he has to sustain; increasing or diminishing, however, by another law, the difficulty of pushing forward the barrow, according to the weight on the fulcrum.

Two men carrying a load between them on a pole is also an example of the second kind of lever. The load may either rest upon, or be dependent from, the pole. In the case of two porters carrying a sedan-chair by means of two poles, the load or weight is partly above and partly below the line of the lever. In the case of porters carrying a barrel slung from a pole, as in fig. 12, the weight is altogether below the lever. In both instances, the principle is the same. Each man acts as the power in lifting the weight, and at the same time each man becomes a fulcrum in respect to the other. If the weight hang fairly from the centre of the pole, each man will bear just a half of the burden; but if the weight be slipped along, to be nearer one end of the lever than the other, then the man who bears the shorter end of the pole supports a greater load than the man who is at the long end. The weight increases precisely in proportion as it advances towards him. Sometimes, when a man and a boy are carrying a hand-barrow between them, the man, in order to ease the weight as much as possible to the boy, holds by the arms of the barrow near to where they join the loaded part. In yoking horses to the extremities of cross-bars in ploughs, coaches, or other vehicles, if the cross-bar is not attached to the load by its middle point, one horse will have to pull more than the other.

Fig. 12.

An inflexible beam, resting on supports or fulcra at its two extremities, acts similarly to a lever of the second kind. Should no weight be appended to its centre, the weight of the material itself, when the extension is considerable, will be enough to bend it down, and even to break it. Extended flexible cords or chains are from this cause always bent down in the middle, no power of extension being able to overcome the gravity of the materials, acting at such an advantage of lever power.

The instrument used for cracking nuts (fig. 13) is an example of the second kind of lever with two arms or limbs. The fulcrum is the joint which connects the two limbs; the nut between them is the weight or resistance; and the hand which presses the limbs together, in order to break the nut, is the power. As each limb is a lever, a double lever-action takes place in the operation. The oar of a boat in rowing is also a lever of this kind. The hands of the sailor who pulls, constitute the power; the boat is the weight to be moved; and the water against which the blade of the oar pushes, the fulcrum.

Fig. 13.

In a lever of the third kind, the power must, from its position, be always greater than the weight; and from this circumstance it has sometimes been called the *losing* lever. But this gives a wrong impression; for what is lost in the amount of the power is gained in the velocity, or in the space over which the resisting weight is made to move. Levers of this kind are used where the object is not to gain power and overcome great resistance, but to produce rapid motion where the resistance is comparatively small.

An example is found in the footboard of the turning-lathe (fig. 14). The foot of the workman presses on the board or plank near the end which rests on the ground, or fulcrum, and, at the cost of a short movement of its own, causes the opposite extremity of the board to move in a downward direction over a considerable space.

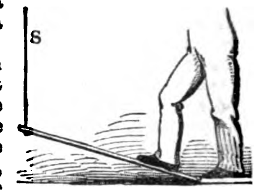

Fig. 14.

When earth is lifted on a spade, if the hand at the extremity of the handle is held fixed while the other makes the spade turn upon it as a centre, we have a lever of the third kind. If the hand that grasps the handle at some distance from the end is held fixed, and the other communicates the motion, it is a lever of the first kind. In practice, both hands move, acting reciprocally as power and fulcrum to each other. In using a pitchfork, a pencil, a pen, &c., the first and third levers are similarly combined.

The movements in the limbs of animals are mostly produced by the action of levers of the third kind. The tendons or ropes which move the bones are attached near the joints, which are the pivots or fulcra of the bone-levers. A striking instance is exhibited in the human arm. A strong muscle, arising in the shoulder, passes down in front over the joint of the elbow, and is inserted into one of the two parallel bones which compose the framework of the forearm, or from the elbow to the wrist. On being contracted in the slightest degree, at the impulse of the will, this muscle (the *power*) elevates instantaneously the hand (the *weight* or resistance) to the shoulder, bending the arm upon the elbow-joint (the *fulcrum*). Fig. 15 illustrates perfectly this mechanism of the arm. F represents the elbow-joint; P the power or will acting over, or from, the shoulder S, through the contracting muscle M; and B the arm from the hand to the elbow; while the weight W is an object supposed to be placed in the hand.

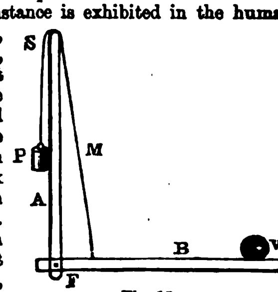

Fig. 15.

Nothing can better illustrate the characteristic advantages of levers of the third kind than this action in the human arm. The contraction of the muscle, to the extent of only one inch, raises the hand, even with a very considerable weight in it, through a semicircle of twenty-one inches; and by relaxing the muscle only a little, the hand, as represented in fig. 16, is allowed to drop over a similarly wide range. No doubt other muscles in the arm assist in this action, but the principal part is performed by the one described, and here indicated by the letter M.

It is worthy of observation, that in the second of these figures, illustrating the mechanism of the arm, the lever-power acts under increased disadvantage, from the greater inclination of the limb than in the preceding figure. We can raise or sustain a much larger weight with the hand when the arm is bent at right angles, than when it is extended nearly in a straight line; and the more the arm is stretched out, the more is the power diminished. What is gained, however, in force, is necessarily lost in extent of motion.

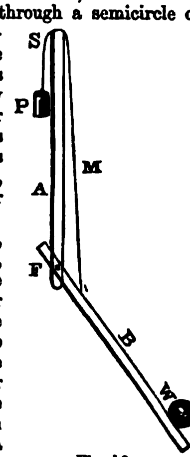

Fig. 16.

Compound Levers.

When several levers of the simple kinds are connected together, and are made to operate one upon the other, the machine so formed is called a *compound lever*. In this machine, as each lever acts with a power equal to the pressure on it of the next lever between it and the power, the force is increased or diminished according to the number or kind of levers employed. Fig. 17 represents a compound lever, consisting of three simple levers of the first kind, placed in a line, and each working on its own fulcrum. The same principle applies, in

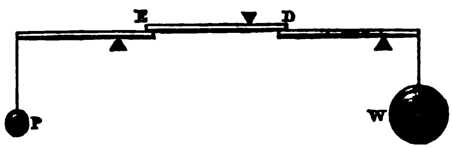

Fig. 17.

calculating the action of this combined lever, which holds for the simple lever.

It is supposed that the three levers in the figure are of the same length, the long arms being six inches each, and the short ones two inches each; required—the weight which a moving power of 1 pound at P will balance at W. In the first place, 1 pound at P would balance 3 pounds at E, according to the rule of calculation for the simple lever; for $1 \times 6 = 3 \times 2$. This upward pressure of 3 pounds at E, is next converted, by the second lever, into a downward pressure at D three times as great, or equal to 9 pounds; and, lastly, the downward pressure of 9 pounds at D is converted, by the third lever, into an upward pull at W of 3 times 9, or 27 pounds. Thus, 1 pound at P will balance 27 pounds at W; or, 1 ounce at P will balance 27 ounces at W—the proportions being always alike, whatever denomination of weight we employ.

In this instance, the increase of power is comparatively small, because the proportion between the long and short arms is only as 2 to 6, or 1 to 3. If we make the proportions more dissimilar, as 1 to 10, or 1 to 20, the increase of force becomes very great. For example, let the long arms be 18 inches each, and the short ones 1 inch each, and 1 pound at P will balance 18 pounds at E, and the second lever would be pushed up with a power of 18 pounds. This 18 being multiplied by 18, the length of the second lever, gives 324 pounds as the power which would press down the third lever. Lastly, multiply this 324 by the length of the third lever, 18, and the product is 5832 pounds, which would be the final weight at W, which 1 pound at P would raise.

The following is a general rule for calculating the advantages of a compound lever consisting of any number of levers, whether equal or not:—Call the arms of the different levers next the power the *arms of power*, and the other arms the *arms of weight;* then, if the lengths of the arms of power and the power itself be multiplied together, the product will be equal to the continued product of the arms of weight and the weight, when the power and weight are in equilibrium.

A similar result to that of a combination of levers might be produced by only one lever, provided it were long enough; but the operation would be both clumsy and inconvenient. By combining levers, and making them act one upon another, great weights may be balanced within a small compass, and with an exceedingly small power. On this account, machines are constructed with combinations of levers for weighing loaded carts and other heavy burdens. The cart is wheeled upon a sort of table placed level with the ground, beneath which the levers are arranged; and a small weight placed on a scale attached to the extreme point of the first lever balances the load, which rests on the table above the last lever. This species of weighing-machine is often to be seen at toll-bars.

Bent Levers.

In the foregoing examples of lever-power, the levers or bars are supposed to be straight, and the powers and weights, or forces, are supposed to act at right angles with them. But levers are frequently *bent* in their form, for purposes of convenience, and the powers and weights often act *obliquely*, or not at right angles.

In calculating the mechanical advantage, the chief matter for consideration is *obliquity* in the direction of the applied power and weight. Obliquity in the action of the forces generally diminishes the mechanical advantage. Whatever be the form of the lever, or the direction of the power and the weight, the mechanical advantage of the power or the weight is always represented by *a line drawn from the fulcrum, at right angles to the direction in which the forces are respectively exerted.*

Fig. 18 is a bent lever, with the power P hanging from A, and the weight W hanging from B. In this case, both the power and the weight act at right angles to an ideal line, drawn as from E to G across the fulcrum, which strikes the lines of direction of the forces at right angles. This ideal line therefore represents the true lever of calculation, and we proceed with it according to the ordinary rule for calculating lever-powers. In this manner the bending goes for nothing.

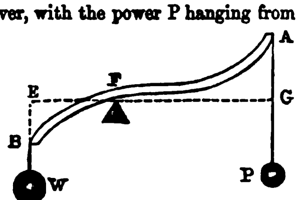

Fig. 18.

Fig. 19 is a straight lever with the power P acting obliquely from D to A, and the weight W acting obliquely from G to B. In order to calculate the power of this kind of lever, we must draw lines as represented in fig. 20. First, we draw a line obliquely upwards in the direction of the pulling-power. This line is seen dotted from A to M. We then draw a line off from it, or *at right angles* with it, to F, the fulcrum. This line is seen dotted, and marked H. We next draw a line obliquely upwards in the direction of the pull of the weight, as from B to N; and in the same manner as before draw a line *at right angles* from it. This line is seen dotted, and marked K. We have now found an ideal lever, with two arms, H and K. This ideal lever is the true lever of calculation, and we proceed with it according to the ordinary rule for calculating lever-powers.

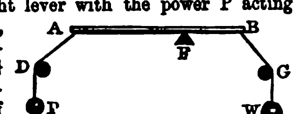

Fig. 19.

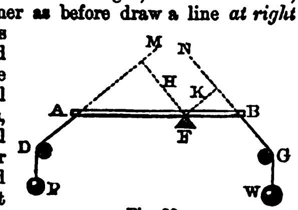

Fig. 20.

Sometimes the lever is bent in such a manner that the long arm rises perpendicularly from the fulcrum, as in fig. 21. In this case the upright long arm from F to A acts precisely as if it were horizontal, because the power or hand is supposed to act at right angles to the arm. If we were to draw an ideal line from the top of the arm at A directly downwards to F, it would descend straight through the arm, and hence in this case there would be no use in drawing it. The calculation may be made with the arm itself.

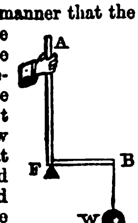

Fig. 21.

But if the power be made to draw obliquely downward, or not at right angles to the line from the fulcrum, we must draw an ideal line, as represented in fig. 22. The line of direction of the power is seen proceeding obliquely from A to the hand P. A dotted line H is drawn at right angles from this line to F, the fulcrum; the line H therefore represents the true arm of power of the lever.

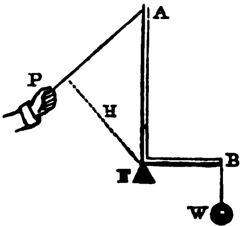

Fig. 22.

A pronged hammer employed to extract a nail, is an example of a bent lever, resembling those just mentioned.

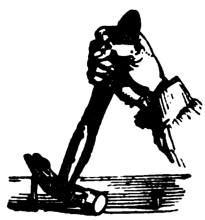

Fig. 23.

From the examples now given, it will be observed that, whatever be the shape or bending of the lever, and whatever the degree of obliquity of the applied force, the power of the machine may be calculated by drawing ideal lines at right angles from the lines of the forces to the fulcrum, and making the calculations from them.

THE WHEEL AND AXLE.

When a lever is movable upon an axis, and is susceptible of being turned completely round, it assumes the character of the diameter of a wheel. AB (fig. 24) is an equal-armed lever, fixed on an axis F. A force acting at A or B, if not held in equilibrium, would continue to turn the lever round and round.

Fig. 24.

Let another lever CD (fig. 25), with arms of the same length, cross AB, turning on the same axis and fixed to AB, so as to form a solid system; it will be indifferent whether a force act at A, C, B, or D; it will have the same effect in turning the system on the common axis. The same is true of any number of levers crossing one another; and if a ring is made to unite their ends, like a wheel, a force acting at any point on the ring, will have the same effect as if it acted at the end of one of the levers. A wheel is thus a system of equal-armed levers crossing one another in the centre.

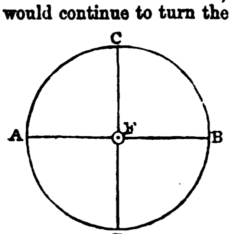

Fig. 25.

The way in which such a system is turned to account as a moving power is represented in fig. 26. A wheel is fixed on an axle, the ends of which turn in upright supports. A cord is wound round the wheel, and another round the axis in the opposite direction. If a weight, P, is then attached to the cord of the wheel, it will by its descent turn the wheel, and the axle with it; and the winding of the cord on the axle will lift the weight W attached to it. This is the machine called the *wheel and axle*, which may be characterised as a *perpetual lever*.

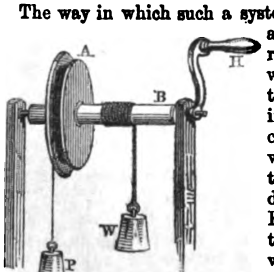

Fig. 26.

Fig. 27, presenting a section of the wheel and axle, shews the lever-power, with which the two forces act. F, the centre of both wheel and axle, is the fulcrum; AF, half the diameter of the wheel, is the distance from the fulcrum or arm, at which P acts; and FB, half the diameter of the axle, is the arm at which W acts. Thus, the larger the wheel, and the smaller the axle, the greater advantage the power has over the weight. But this advantage in power is gained at the sacrifice of speed, for every turn of a small axle raises the weight but a short way.

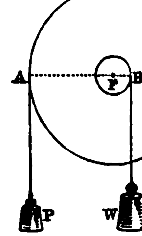

Fig. 27.

Instead of a wheel and weight, the axle may be turned by a handle H (fig. 26). The handle is just part of a wheel, and the force of the hand that turns it acts at an advantage proportioned to the wideness of the circuit it makes.

The proportion of the power to the weight in the wheel and axle is calculated precisely as in the case of the simple lever. If the diameter of the wheel is six times that of the axle, or, which is the same thing, if the circumference of the wheel is six times that of the axle, a power of one pound will raise a load of six pounds.

The principle of the wheel and axle, or perpetual lever, is introduced into various mechanical contrivances, which are of great use in many of the ordinary occupations of life. One of the simplest machines constructed on this principle is the common windlass for drawing water by a rope and bucket from wells. Coal is lifted from the pits in which it is dug by a similar contrivance, wrought by horse or steam power.

The capstan in general use on board of ships for hauling or drawing up anchors, and for other operations, is an example of the wheel and axle, constructed in an upright or vertical, instead of a horizontal, position. In fig. 28, one of these capstans is represented. The axle is placed upright, with the rope winding about it, and having a head pierced with holes for spokes or levers, which the men push against to cause the axle to turn. This is a powerful and convenient machine on shipboard; when not in use, the spokes are taken out and laid aside.

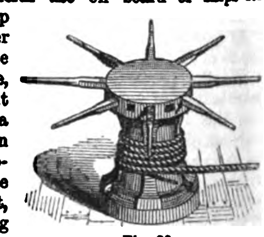

Fig. 28.

PULLEYS.

The pulley consists of a small wheel, called a *sheave*, turning on an axis in a block, with a flexible cord resting in a groove in the circumference of the wheel. There are two kinds of pulleys—the *fixed* and the *movable*.

The annexed cut represents a pulley, A, fixed by its block or frame to a beam or roof, B, and having two weights attached to the ends of the cord. In order that P and W may be in equilibrium in this case, it is evident that they must be equal. This appears from the wheel being a lever with equal arms, so that neither P nor W has any advantage. It is also plain that the cord, being free to move either way, must be equally stretched, or have the same *tension* throughout its whole length. A fixed pulley does not increase the power; it only serves to change the direction in which the power acts. This is often as great a gain as increase of power would be. A force, for instance, at P, pulling downwards, can raise W upwards.

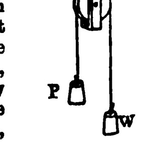

Fig. 29.

The same object might be gained by bending the cord

over a fixed bar, and making it slide on it; but in this case the friction of the cord on the surface of the bar would cause great resistance, and would chafe the cord; and to obviate this is the use of the sheave. Theoretically, then, the whole virtue of the pulley resides in the flexible cord.

The movable pulley is generally attached to the weight or resistance, and moves along with it. In the annexed cut, a cord is carried from a fixed point at A round a pulley B, from which the weight is suspended; it is then made to pass over a fixed pulley at C, and the power is represented by a hand drawing downwards. The parts of the cord BA and BC being equally stretched, each sustains evidently *half* the weight; but the part of the cord PC has the same tension as the rest, therefore P pulls down with a force equal to half the weight. A single movable pulley, then, *doubles* the effect of the power. The only effect of the fixed pulley C is to change the direction; if the hand were at C pulling upwards, it would sustain just half the weight.

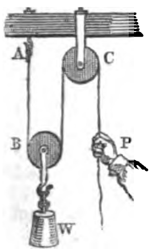

Fig. 30.

In order to save expenditure of power in lifting weights by pulleys, it is always contrived to cause some inanimate object—as, for instance, a beam or roof—to take a share of the weight, leaving only a portion to be borne by the person who pulls. But in this, as in all cases of mechanical advantage, the saving of power is effected only by a certain loss of time, or a longer continuation of labour. To lift a weight one foot from the ground by the movable pulley, a man must pull up the cord two feet.

As represented in fig. 31, a man may seat himself in a loop or seat attached to one end of a cord, and passing the cord over a fixed pulley above, may pull himself upwards by drawing at the other end of the cord. He requires to support with his arms only a little more than half the weight of his body in order to make the seat ascend. By adding a movable pulley and another fixed pulley to the apparatus, the exertion of pulling would be diminished one-half. An apparatus of this nature, having two fixed pulleys and one movable pulley, is used by masons and other artisans in making repairs on the fronts of buildings.

Fig. 31.

In all cases in which cords are drawn tightly, so as to hold objects in close contact, the same species of power or mechanical advantage is exemplified. For instance, in drawing a cord in lacing, or a thread in sewing, this distribution of strain is observable. If all the force of tension which is distributed throughout the sewing of a single pair of strong shoes were released and concentrated in one main draught, it would in all likelihood be a power sufficient to lift one or two tons in weight.

Technically, the wheel of a pulley is called a *sheave;* for protection and convenience, this sheave is ordinarily fixed with pivots in a mass of wood called a *block;* and the ropes or cords are called a *tackle.* The whole machine, fully mounted for working, is termed a *block and tackle.* By causing a wheel and axle to wind up the cord of a block and tackle, the power of the lever is combined with that of the pulley in the operation.

The power of pulleys is increased by a combination of wheels or sheaves in one tackle. There are different kinds of combinations or systems of pulleys. In some there is only one fixed pulley, and in others there are several. The following are examples of different combinations of pulleys:—

Fig. 32 represents a compound system of pulleys, by which the weight is distributed through four folds of the same cord, so as to leave only a fourth of the weight, whatever it may be, to be raised by the operator. In this illustration, the cord number 1 bears one-fourth of the weight; the cord number 2 bears a second fourth; the cord number 3 bears a third fourth; and the cord number 4 bears a fourth fourth. Here the mechanical advantage ceases. For although the cord number 4 passes over the topmost fixed pulley down to the hand of the operator, no more distribution of power takes place; this topmost pulley being of use only to change the direction of the power. The person who pulls has thus only a quarter of the weight to draw. If the weight be 100 pounds, he has the labour of pulling only 25 pounds. If there were 3 pulleys in the lower block, the power would be $\frac{1}{6}$ of the weight; if 4 pulleys, $\frac{1}{8}$; and so on; but every such addition causes more time to be spent in the operation, there being at every additional fold of the cord more cord to draw out, and also more friction to overcome.

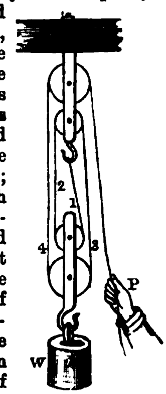

Fig. 32.

In the annexed system of pulleys (fig. 33), a series of movable pulleys, with different cords, are made to act successively on one another, and the effect is doubled by each pulley. At the extremity of the first cord, a power of one pound depends. This cord, marked 1, by being drawn below a movable pulley, supports two pounds—that is, 1 pound on each side. The next cord, marked 2, in the same manner supports four pounds, or 2 pounds on each side. The next cord, marked 4, supports eight pounds, or 4 pounds on each side. Thus, 1 pound at P supports 8 pounds at W. If another movable pulley were added, the 1 pound at P would support 16 pounds; and so on.

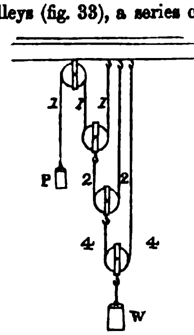

Fig. 33.

In working pulleys, the power must be applied in a line perpendicular to, or parallel with, the weight—that is, straight above the weight—in order to produce the full efficacy of direct force. If the power be applied obliquely, there will be a loss of power in proportion as the line of draught departs from the perpendicular.

Pulleys are used chiefly on board of ships, where blocks and tackle are in constant requisition for raising and lowering the sails, masts, and yards. They are likewise in considerable use by house-builders and others, in connection with the wheel and axle, for raising or lowering heavy masses of stone and other articles.

Fig. 34 is a representation of a system of pulleys commonly used in practical operations. Three movable pulleys are enclosed in the block A, and three fixed pulleys are enclosed in the block B. Suppose, therefore, that the weight W, in this case, is 600 pounds, the hand P pulls it upwards by exerting a force of 100 pounds. A combination of pulleys resembling this is used in turning kitchen-jacks. The weight in

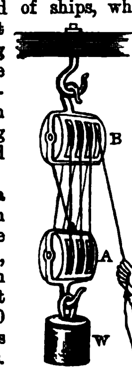

Fig. 34.

sinking draws off the cord from a spindle, by which motion the jack is turned. In order that a considerable weight falling slowly through a comparatively small height may keep the jack in motion for a long time, as many as ten or twelve movable and fixed pulleys are used.

THE INCLINED PLANE.

If AB represent a horizontal plane, AC will represent a sloping or *inclined* plane. If we suppose AC to be a plank resting on the ground at A, and with its other end at C on the edge of a dray-cart, a man can roll a heavy cask from A to C, which it would be far beyond his strength to lift perpendicularly from BC. In such a case the inclined plane is used as a mechanical power.

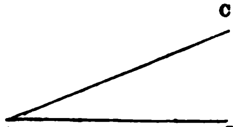

Fig. 35.

In investigating the advantage afforded by the inclined plane, we consider, as in all the other mechanical powers, what force is necessary to hold the weight in equilibrium—in other words, what force is necessary to keep the cask, when once on the plane, from rolling down. When it is once balanced in this way, a little additional force will make it move up. In practice, if the heavy body to be moved up is of a square shape, as a box, its own friction is sufficient to keep it from sliding down, unless the elevation is very great; and to push it up requires force to overcome this friction, in addition to what would be necessary to push up a round body of the same weight. But for the theory of the inclined plane, we consider bodies as moving without friction; and this is most easily conceived by representing them either as round, or as resting on wheels, because a rolling motion is attended with comparatively little friction.

When a round cylinder rests on a level plank, its whole weight is supported by the reaction of the plank, and it has no tendency to roll either way; but if one end of the plank be raised, however slightly, the cylinder begins to roll, and a certain force is required to keep it at rest. As the end is more and more elevated, the restraining force requires to be increased, and at the same time the pressure on the plane becomes less, until, when the plank comes into the upright position, it ceases to sustain any pressure, and a force equal to the whole weight of the cylinder is required to keep it in its position.

In order to find the relation of P to W in a given inclined plane, we have recourse to the resolution of

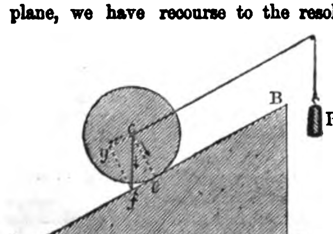

Fig. 36.

forces. In the above fig., which represents a cylinder resting on a plane, and kept from rolling down by a weight suspended over a pulley, let *cf*, drawn from the centre of gravity of the cylinder in a vertical direction, represent the whole weight of the cylinder. This force may be resolved into two others, *ce* perpendicular to the plane, and *cg* parallel to it; but *ce* is counteracted by the resistance of the plane, and can produce no effect; therefore *cg* or *ef* represents the force with which the cylinder is urged in the direction of BA, or the weight of P necessary to keep it from rolling. Now, it can be shewn that the triangle *cfe* is similar to the triangle ABD; therefore *fc* is to *ef* as AB to BD—that is, *W is to P as the length of the plane to its height.* If AB is twice the length of BD, one hundredweight at P will sustain two hundredweights at W; and if AB is six times the length of BD, W will be six times P.

In speaking of sloping roads, they are said to have an inclination or rise of one foot in ten, one in thirty, one in a hundred, and so on. The annexed cut represents

Fig. 37.

a cart drawn by a horse up a road with a rise of one in ten. On a perfectly level road, a certain force of draught would be required to overcome friction; on the incline there is required, in addition to this, a constant pull to counteract the tendency of the cart to run down the slope. That tendency is, in this case, equal to a tenth of the weight of the load; and if the load is a ton, the horse has to pull with a force of one-tenth of a ton, or 224 pounds, above what would have sufficed to draw it along a level.

In going over ten feet of the road, the horse has raised the cart one foot perpendicularly, but he has done it by instalments; the exertion has been spread over a movement of ten feet. Intensity of exertion is saved at the expense of time.

Fig. 38 represents two inclined planes of the same height, but different slopes, meeting together at the top, with a weight resting on each, P and Q, hanging by a string, which passes over the pulley M. If the length of the longest plane from A to M be two feet, and that of the shorter from B to M be one foot, then two pounds at Q, on the short side, will balance four pounds at P, on the long side; and so for other proportional lengths. In this manner, weights moving on two adjoining inclined planes may be adjusted so as to balance each other, although the inclinations be different; and they are so made to act on various sloping railways, where one wagon descending on one plane, is made to draw up another wagon on another plane.

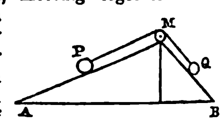

Fig. 38.

In modern times, roads are constructed with as few risings and fallings as possible. When roads have necessarily to be carried to the summits of heights, they are made either to wind round the ascent, or to describe a zigzag direction. The drivers of carts are aware of the saving of violent strain to their horses by causing them to wind or zigzag up steep roads, instead of leading them directly forward.

Fig. 39.

The inclined plane is resorted to in many of the ordinary occupations of life. By it, loaded wheel-barrows

are with comparative ease wheeled to considerable elevations in house-building and other works of art; hogsheads are rolled out of or into wagons, and ships are launched into or drawn from the water, the inclined plane being as useful in giving facilities for letting down loads as in drawing them up.

THE WEDGE.

A common form of the wedge is represented in the figure. By forcing such a body below the bottom of an upright post, for instance, which can move only vertically, we may raise it a few inches. It obviously acts on the principle of the inclined plane; it is, in fact, the inclined plane made movable. A wedge of the ordinary shape is really two inclined planes placed base to base.

Fig. 40.

The proportion of the power to the resistance in the wedge is calculated theoretically in the same way as in the inclined plane. But the theory is of little or no value. The power employed being percussion or blows, cannot be rightly compared with the resistance; it cannot be estimated in pounds, like other forces. The friction, too, is so great as to render any precise statement of proportion impossible. In a general way, however, the wedge is more powerful as the angle is more acute; just as the advantage of the inclined plane increases with the smallness of its height.

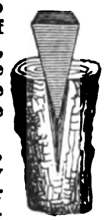

Fig. 41.

The wedge is used in splitting timber, stones, &c. Ships are raised in docks by driving wedges under the keel. In expressing oil from seeds, the seeds are placed in bags between solid pieces of wood, and these are forced together by means of wedges, till the seeds become a mass as compact as wood.

Cutting and piercing instruments all act on the principle of the wedge. The plough is also an instance.

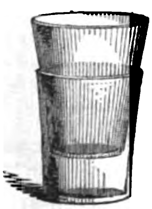

Fig. 42.

The principle of the wedge operates in the case of two glass tumblers, one placed within the other, as in fig. 42. A very gentle pressure applied to the uppermost tumbler would be sufficient to burst the lower.

THE SCREW.

The screw is an inclined plane wound round a cylinder, resembling the spiral road winding round the hill in fig. 39.

Take a cylindrical ruler AB, and cut a slip of paper in the form of a right-angled triangle *abf*, having *ab* equal to the length of the cylinder, and *bf* equal, say to four times its circumference. If the edge *ab* is

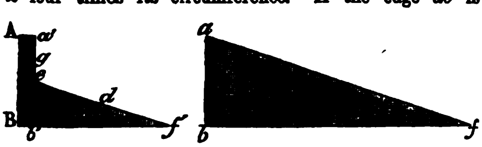

Fig. 43.

applied to the cylinder lengthwise, and the triangle is then wrapped round and round, the slanting side, *af*, will form a spiral going four times round the cylinder before it reach the bottom. In the fig. to the left of the cut, it is represented as half wrapt on.

If a ridge or projection were raised on the cylinder along the spiral line, it would form a screw. The several turns or coils of the spiral are called the *threads* of the screw; *ed* represents the *length* of one thread, and *ec* the *distance between the threads*. In moving over a complete round of the spiral, a perpendicular ascent or descent is made equal to *ec*. As in the inclined plane, therefore, the mechanical advantage of the screw must be greater in proportion as the length of a thread exceeds the distance between two contiguous threads.

In using the screw as a machine, the resistance is not applied directly to the spiral surface, as in the wedge or the straight inclined plane; the screw is made to work in a hollow cylinder with spiral grooves cut out to correspond to the projecting threads. This concave screw is technically called a *nut*, as represented at M, fig. 44. The threads and corresponding grooves are sometimes of a triangular form, as in fig. 44; and sometimes flat, as in fig. 45.

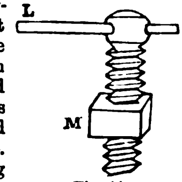

Fig. 44.

To produce pressure with the screw, either the screw or the nut must be fixed. Whichever is free, is then turned, and made to press against the resistance.

Practically, the screw is never used as a simple machine; the power being always applied by means of a lever, passing either through the head of the screw or through the nut. The screw therefore acts with the combined power of the lever and inclined plane; and in investigating the effects, we must take into account both these simple mechanical powers, so that the screw now becomes really a compound machine.

Fig. 45.

To arrive at the proportion of the power to the weight in this compound machine, we may apply the principle of virtual velocities. The power acts at the end of the lever L (fig. 44), and in turning the screw once round, it describes a circle, of which the lever is the radius. The circumference of this circle represents the velocity of the power. In the meantime, the weight has moved over a space equal to the distance between two threads, which is its velocity. Now, the power multiplied by its velocity, is always equal to the weight multiplied by its velocity; therefore, *in the screw, the power multiplied by the circumference it describes, is equal to the weight multiplied by the distance between two contiguous threads.*

The length of the lever of a screw is forty inches—counting from the centre of the screw—and the distance between the threads is one inch; what power will produce a pressure of 8000 pounds? The diameter of the circle described by the power is here eighty inches, and the circumference may be taken, in round numbers, at three times that, or 240 inches. The product of the weight into the distance between two threads is $8000 \times 1 = 8000$; the power must therefore be $8000 \div 240 = 33\frac{1}{3}$ pounds. This, however, is only in theory; in practice, the power must be increased by a third, for the purpose of overcoming the friction; it would in this case, then, be about forty-four pounds.

It is evident that the power of a screw increases with the closeness of its threads—that is, with its fineness; but this way of augmenting the force soon comes to a limit, because the threads, if too fine, bend or break off—the screw overdraws. To obviate this is the object of a contrivance called, from its inventor, the Hunterian screw. It consists of two screws whose threads differ slightly in breadth. The smaller of the two is made to work into the other as a nut, and one turn of the outer screw in its nut advances the end of the inner screw by a space equal to the difference between the breadths of the two sets of threads. Thus, if there are six threads in the inch of the outer screw, and seven in the inner, the advance caused by one revolution is $\frac{1}{6} - \frac{1}{7}$, or $\frac{1}{42}$ of an inch. The power is thus the same as if the screw had been single, with forty-two threads in the inch; while at the same time the threads are large and strong.

The most common purpose for which the screw is applied in mechanical operations, is to produce great pressure accompanied with constancy of action, or retention of the pressure; and this quality of constancy is always procurable from the great friction which takes place in the pressure of the threads on the nut, or on any substance, such as wood, through which the screw penetrates. The common standing-press used by bookbinders for pressing their books affords one of the best examples of the application of the screw to produce great pressure (fig. 46). The screw A has a thick round lower extremity B, into holes in which the lever is inserted. This extremity B is attached by a socket-joint to the pressing-table C, so that when the screw is turned in one direction, the table sinks, and when turned in another, the table rises. The books D lie upon a fixed sole S, and are thus between the table and the sole. H is a cross-beam above, in which is the box or overlapping screw, to give the necessary resistance.

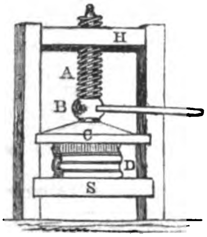

Fig. 46.

The force of the screw is sometimes employed to turn a wheel by acting on its teeth, by which means there is a combination of two mechanical powers — the screw, and the wheel and axle (fig. 47). The screw is upon the horizontal spindle, and by turning it by the handle, each turn of the thread receives a tooth of the wheel, and brings it forward, so as to produce a perpetual revolution of the wheel. This is called an endless screw, because it never stops in its action; no sooner is one turn of the thread disengaged, than another has come into operation. W represents a weight to be raised hanging from the circumference of the axle.

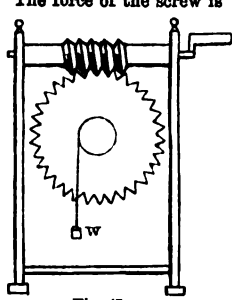

Fig. 47.

STRENGTH OF BODIES AND OF STRUCTURES.

A knowledge of the simple principles of mechanics above considered, together with that of the general properties of matter, enable us to determine what forms of bodies and what positions are best calculated to resist forces that tend to break, crush, or overthrow them. This constitutes engineering. A few of the more important general truths thus arrived at may be here noticed; their applications are treated of in a separate number.

One regards the best shape of a beam to resist a transverse strain—that is, a force tending to break it across. When a rod of wood is suspended vertically, and a weight attached to it tending to tear it asunder, all its fibres act equally, and its strength evidently depends on the strength of the individual fibres and their number—that is, the area of the cross section of the rod. If there are two rods, then, of the same material, the one having an area of one square inch in its cross-section, the other an area of three square inches, the last will sustain three times the weight that the other will sustain, and this whatever be the shapes of the sections. The section of the one rod may be circular, square, oblong, triangular, &c., and that of the other any other shape.

But it is different when a rod or beam resists a force laterally. In fig. 48, a beam is represented supported at the two ends, and breaking by a weight resting upon it. The fracture opens as if a hinge were placed at *d*; and if we consider *ge* and *hf* to be two fibres drawn out by their elasticity just before their rupture, we see that they exercise very different forces in resisting the

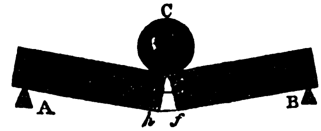

Fig. 48.

fracture of the beam. *hf* acts at the ends of the long levers, *hd* and *fd*, while *ge* acts at the ends of levers of half the length. The effect of any fibre, then, in resisting the fracture, is equal to its absolute strength multiplied by its distance from *d*; and their collective effect is equal to the sum of their absolute strengths multiplied by their *mean* distance—that is, by the distance of the centre of gravity of the section below the point *d*.

Let A and B represent sections of two beams, A being a square of ten inches each way, and B having half the breadth and twice the depth. The number of fibres in each is as the area; and the area of A is $10 \times 10 = 100$; of B, $20 \times 5 = 100$. But the effective force of the fibres is as their number multiplied by the distance of the centre of gravity from the end of the fracture. The strength of A, therefore, is 100×5 (the length of *cg*) $= 500$; and that of B is 100×10 (the length of *dg*) $= 1000$. The beam B has thus double the strength of A, although they both contain the same quantity of material. It is on this principle that the rafters of floors, roofs, &c., are not made square, but as deep and thin as may be without yielding laterally. Strength is thus gained and material saved.

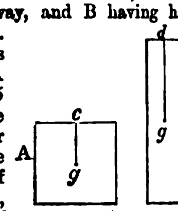

Fig. 49.

For the same reason, a hollow cylinder is stronger than the same material made into a solid rod. B is the section of a hollow cylinder, the thickness of whose walls is represented by the shaded ring; A is the section of a solid cylinder of the same material. If the area of A is equal to that of the ring in B, the two cylinders will contain the same quantity of matter, but B will be stronger than A in proportion as *cg* is longer than *dg*; *g* being the centre of gravity of the ring, *cg* is the average advantage or leverage at which the cohesion of the matter of B acts in resisting fracture, as *dg* is the leverage in A.

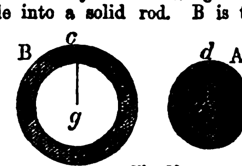

Fig. 50.

It is evident that if the hollow is placed, not in the middle, but nearer the side where the fracture would end, the strength will be increased, because the centre of gravity is thrown to a still greater distance. The limit to this, as well as to the enlargement of the hollow generally, is that the walls must be left thick enough to be rigid and preserve their form.

The principle of hollow structure prevails both in nature and art, wherever strength and lightness have to be combined. It is seen in the stems of plants, especially of the grasses; the bones of animals are also hollow, and those of birds, where great lightness is required, are most so. A feather, with its hollow stem, is perhaps the best instance of the union of strength and lightness that could be given. In art, again, we have hollow metal pillars. And in tubular bridges, the sides, bottom, and roof do not consist of one layer of metal, but of a series of cells or hollows, so that every part has as much lever-power as possible, to resist bending and fracture. Iron ships are now built on the same principle.

Another general truth respecting the strength of

bodies and structures is, that the larger the scale anything is constructed on, the weaker proportionally it is; and the greater tendency it has to fall asunder by its own weight. If the dimensions of a beam are doubled in every way, its strength to resist external pressure is increased fourfold; or the strength increases as the *square* of the dimensions. But by doubling the dimensions, the weight becomes eightfold what it was, or increases as the *cube* of the dimensions. A point is thus soon arrived at where, instead of supporting external force, a beam breaks with its own weight.

This important principle limits the size of machines, buildings, ships, &c.; as well as of trees and animals. The larger an animal is, its limbs are, out of proportion, thicker; the clumsiness of the elephant shews that a much greater size could not exist on our globe. The giants of fable are impossible beings. A small compact man is stronger in proportion to his size than a tall man.

PRACTICAL MACHINERY.

The term *machine* is ordinarily applied to any piece of mechanism in which different parts are combined to produce a desired effect. In NATURAL PHILOSOPHY, a machine of this nature is called a *complex machine;* and the treatment of the principles on which complex machines operate, constitutes that department termed PRACTICAL MACHINERY.

The simple mechanical powers compose the elements of all machines, however complex or extensive. Thus, in all machines, levers, cords, or inclined planes, in their different modifications, are found to be the elementary parts, combined in harmonious union to accomplish certain results.

This department may be treated of under three divisions. 1. The component parts of machines, shewing the method of practically adapting the principles of the mechanical powers; this may be called the department of *construction*. 2. The arrangement and combination of these parts, to effect the variety of mechanical movements for changing the direction or application of motion or force. 3. The scientific principles upon which the various parts are constructed. The first two of these divisions comprise what may be called the department of *mechanical design*, or arrangement, and will be discussed in the present paper only; the last will be found in the paper on MECHANICAL ENGINEERING.

The following are the principal component parts of machinery:—

Shafts.—The axles on which wheels and pulleys are supported are termed *shafts* and *spindles;* the former being applied to axles of large, the latter to those of small dimensions. Shafts are of two kinds—*horizontal* and *vertical*. In fig. 51, *abc* is part of a horizontal

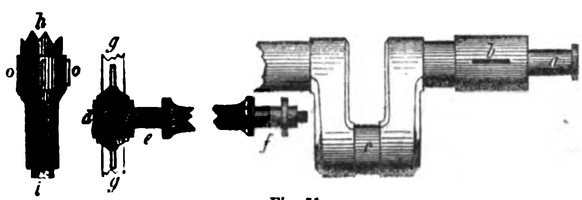

Fig. 51.

shaft; *hi* part of a vertical. The latter is generally used for conveying motion from the lower to the upper part of a machine, or from one story of a mill or factory to the other. The part of a shaft on which it revolves is termed the *journal* or *bearing;* in heavy mill-shafts it is termed sometimes the *gudgeon*. In fig. 51, *a* is the journal of the horizontal shaft *abc*. The journal is formed by turning the shaft to a less dimension than the adjacent parts; thus forming a projection at each end. These projections, as at *f*, are called *ruffs* or *collars*. The part of the shaft on which the wheel is to be fixed is termed the *boss*, as *b* in the horizontal shaft *abc*, and *oo* in the vertical one, fig. 51. The wheel or pulley is fastened firmly on by what are called *keys*, driven into grooves made in the eye, and termed *key-seats*. In fig. 51, *fed* is part of a spindle or small shaft; *f*, *e* are the journals, *d* is the boss, *gg* represents part of a pulley keyed on to the boss. In *hi*, which is part of a vertical shaft, *oo* is the boss, and *i* the bearing.

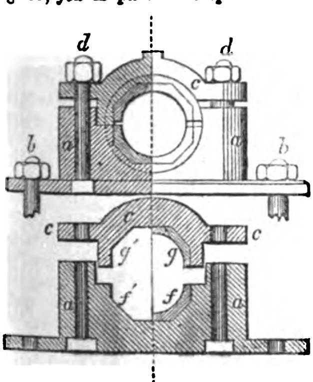

Fig. 52.

Pedestals, or Plummet-blocks, for Horizontal Shafts.—To support the shafts while in motion, *pedestals* or *plummet-blocks* are used. In fig. 52, towards the right-hand side of the centre line of the upper figure, we give a half front elevation of a plummet-block or pedestal; *aa*, the body, is bolted down to the base of the machine by the bolts *b*, *b*. The journal of the shaft is embraced by what are known as *brasses*, *bushes*, or *steps*, made in two pieces or halves, as *g'g*, *f'f*. Fig. 53 gives different views of the brasses: *a* is a front view of the upper brass, *e* a side elevation of the same, and *a'* a section; *b* is an elevation, *d* a side view, and *b* a section of the lower brass; *e* is a plan of both the upper and lower brasses. The breadth of pedestal, body, and cap is such, that they go easily within the projecting flanges, *f*, *f*, of the brasses, as shewn in fig. 53: the brasses are thus prevented from sliding out laterally from the block, as they would be apt to

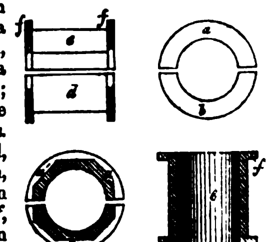

Fig. 53.

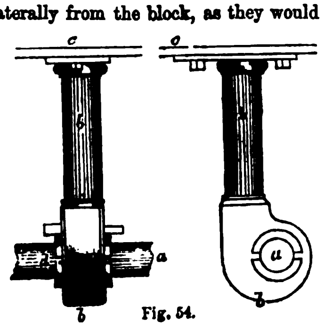

Fig. 54.

do if not furnished with flanges. Shafts are sometimes

required to revolve beneath the ceiling, in order to convey power from one point to another of a building, without interfering with arrangements on the floor below. In this case, *hangers* are used, as shewn in fig. 54. Let *cc* represent the line of ceiling; the suspension bearing is bolted to this, as *bb*: *a* represents the shaft, *d* the brasses in which it revolves.

Steps or Bearings for Vertical Shafts.—A brass block *e*, fig. 55, is placed in the interior of a cast-iron box *bb*, *aa*, which is bolted firmly down to the base, on which the step is supported, generally a block of stone. The position of the brass block *e* is adjusted accurately within the box, so as to make the shaft perfectly vertical, by the adjusting screws *b*, *b*. A hollow is made in the brass *e*, in which the end of the shaft, as *i*, fig. 51, revolves; it being well lubricated by oil poured in, or by tallow which is placed in a space furnished for it in the side of the brass *e*.

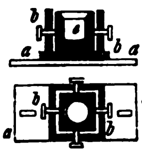

Fig. 55.

Couplings for Shafts.—When the distance to which motion is to be communicated is too great for the employment of one shaft, the several lengths required are joined together by contrivances known as *couplings*. The round coupling, which is most generally used, is illustrated in fig. 56: this, from one end locking into another by the *half-lap joint*, forms a secure coupling. The coupling-box, *c*, is fastened on either by means of *keys*, or by two pins passed through the box and the shaft at right angles to each other, and firmly riveted into countersunk holes made in the box, as shewn at *ac*.

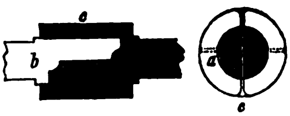

Fig. 56.

Toothed Wheels.—Toothed gearing is divided into two classes—1. spur-wheel; 2. spur-wheel and pinion, and bevelled gear. Fig. 57 represents two spur-wheels in

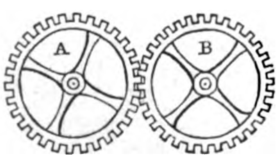

Fig. 57.

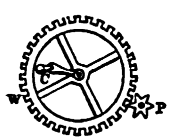

Fig. 58.

gear; fig. 58, a spur-wheel and pinion; and fig. 59, two bevelled wheels in gear. For a brief investigation of

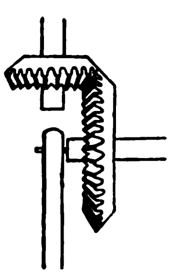

Fig. 59.

the principles which regulate the construction of toothed wheels, see section on Machinery, in the number on MECHANICAL ENGINEERING.

Pulleys.—When motion is transferred from one point to another by means of belts, chains, &c., pulleys are used. In fig. 60, *a* is the front, and *b* the edge view of the pulley used with the flat leather belt. The periphery of the pulley is made convex; this prevents the belt from slipping off, as its tendency is always to keep to the highest part: *c*, *e*, are sections of a pulley, shewing the method of fixing on the shaft; *d* is the form of pulley

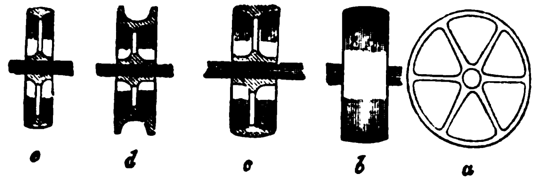

Fig. 60.

used when chains or ropes are made to transmit the power.

Ratchet-wheels.—It is sometimes necessary to prevent wheels and axles, bearing the strain of heavy weights, from flying in a backward motion after being wound up. This purpose is effected by fixing a ratchet-wheel to the extremity of the axle. This wheel has teeth all round its periphery, inclining in one direction; and a small catch is so placed as to enter the indentations, and stop the wheel if it inclines to turn backwards; but the catch slides over the teeth without obstructing them, if it moves forward. A spring pressing on the catch causes it to keep in its proper place (fig. 61).

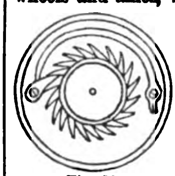

Fig. 61.

Cranks.—A crank resembles a common handle or winch for turning a machine by the hand; the chief difference being that a rod or shaft jointed to the handle, and going up and down, works the machine. Fig. 62 represents a double crank in action. S is the rod or shaft ascending and descending, and attached by a joint to the lower part of the crank C, which it alternately pulls up and pushes down, so as to cause the axles W, W to turn a wheel at each side. Take away one of the sides of the crank and its support, and the apparatus becomes a single

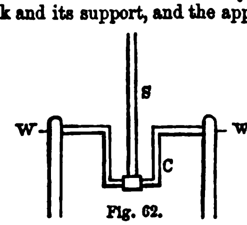

Fig. 62.

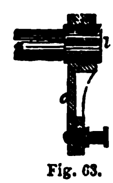

Fig. 63.

crank. In fig. 63, we give a section of the crank of a steam-engine. *c* is the crank keyed on to the boss *b* of the shaft *a*; *d* is the crank-pin, to which the connecting-rod is attached, which gives motion to the crank-shaft *a*.

Connecting-rods.—In various mechanical movements,

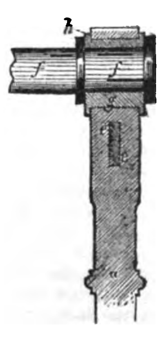

Fig. 64.

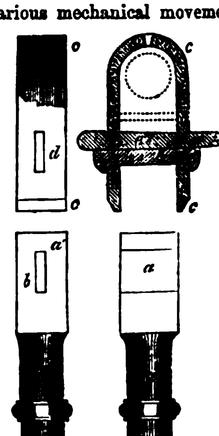

Fig. 65.

motion is communicated from one point to another by

means of connecting-rods. The details of this part of mechanism are shewn in figs. 64, 65, and 66. In fig. 65, *aa* is the front view of *butt* of upper end of connecting-rod, and *a'a'* the side view; *cc* the side view of the strap, and *c'c'* the front view. The journal *f*, fig. 64, is embraced by two brasses, the upper of which is shewn at *a*, fig. 66, and the lower at *b*; *a'* and *b'* being side views of these: in fig. 64, *g* is the lower, and *f* the upper brass. An inspection of the figures will shew how the whole are put together.

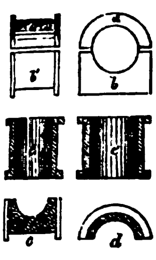

Fig. 66.

Eccentrics.—An eccentric is a wheel or pulley, with the axis out of the true centre. The construction of this is shewn in fig. 67. It consists of a pulley *aa*; the

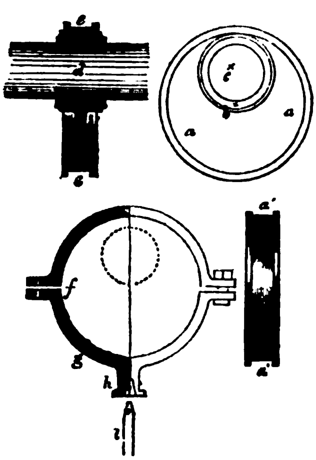

Fig. 67.

periphery of which is grooved, *a'a'*. The true centre is at *b*, but the working-centre, or that through which the axis or shaft *d* passes, is at *c*. In the course of its revolution, any point on its circumference will alternately rise and fall; the extent of which rise or fall is just double the distance which the centre *c* is from the true centre *b*. This alternate motion is communicated to the shaft or lever *l*, by causing two rings, *f*, *g*, to the lower of which the lever *l* is fixed by insertion into the part *h*, to embrace the periphery *a'a'* of the eccentric, so as to allow it to revolve easily within the rings or hoops. The motion is thus communicated to them without causing their revolution.

MECHANICAL MOVEMENTS.

Altering the Direction of Motion.—The use of bevel-wheels, as illustrated in fig. 59, is a very common mode of changing the direction of motion, the horizontal motion of one shaft giving the vertical motion of another.

Where two pulleys work together by means of belts or driving-straps, the driven pulley moves in the same direction as the driving: to change the direction of the driven pulley, all that is necessary to be done is to cross the belt, as illustrated by fig. 68. The same change of direction is effected by using spur-wheels, as in fig. 57; the driven wheel revolving in the opposite direction from that of the driving.

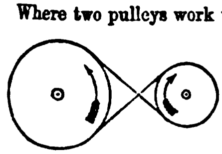

Fig. 68.

Altering the Velocity of Motion.—Where the driven shaft is required to move at a different velocity to that of the driving, it may be effected either by the use of pulleys or toothed wheels of different diameters.

Any degree of velocity greater than that of the first rotary motion, may be imparted to the parts of a machine, by making these parts so much smaller than the primary moving parts.

Preserving the Direction of the Original Motion.—Where two wheels, as in fig. 57, gear together, they revolve in opposite directions—the driven opposite to the driving. By adopting the contrivance of the *annular-wheel*, as in fig. 69, the motion of the driven wheel *aad* is the same as that of the driving-wheel *b*. By placing a third wheel between two toothed wheels, the motion of the third wheel is the same as that of the first.

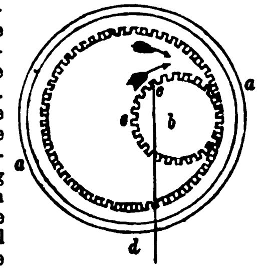

Fig. 69.

Transmission of Power from One Point to Another.—A common plan of transmitting power from one point to another, when the interval is considerable, is by a flat leather band, strap, or belt, communicating from a wheel at the source of power to a wheel connected with the machine, as in fig. 70.

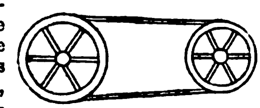

Fig. 70.

Changing or Varying the Velocity of Motion.—It is sometimes necessary that a machine, or part of a machine, should be propelled with a velocity which is not equable, and is continually changing from fast to slow, and slow to fast. This happens in cotton-mills, where it is necessary that the speed of certain parts of the machinery should continually decrease from the beginning to the end of an operation. To effect this, an apparatus is used, as represented in fig. 71. The belt is moved alternately from right to left, from one end of the drum to the other; as it thus acts on circles of continually changing diameter, it causes a continual change in the velocity of the shafts.

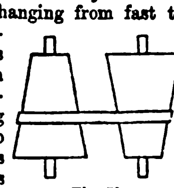

Fig. 71.

The speed-pulleys in fig. 72 is a very usual method of changing the velocity of shafts. Thus, when the belt is passed over *c* and *d*, the velocity of the shaft *fed* is less than that of *abc*; while over *a* and *f*, the condition is reversed.

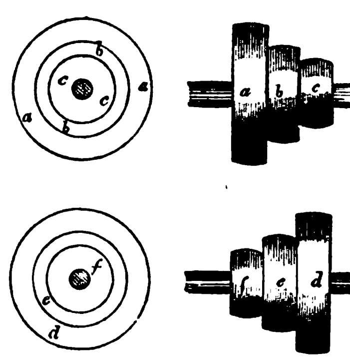

Fig. 72.

Intermittent and Alternating Motions.—Suppose the pinion *a*, fig. 73, to be furnished with teeth for part of its periphery only; the rack *b* will move only as these teeth come in contact with those of the rack. By making the pinion move alternately in different directions, the rack *b* will have an alternate motion to right and left. The stamper or weight *c*, fig. 74, will have an intermitting movement given to it by the cambs of the wiper-wheel *ab*; the weight will rise and fall twice during one revolution of the wiper-wheel *ab*.

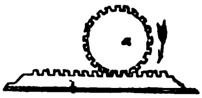

Fig. 73.

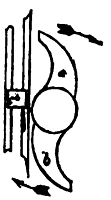

Fig. 74.

Another example of this movement is given in fig. 75. The object required is to work a heavy hammer upon an anvil for beating iron. W is the wheel with the three cambs, and it turns by an axle in upright supports. In turning, each camb, with its rounded or convex side, presses down the end of the handle of the hammer, so as to raise the heavy head H at the opposite end. After pressing down the handle, and escaping, the head of the hammer falls with a heavy blow on the anvil A. There it remains till raised up and let fall by the next camb; and so on.

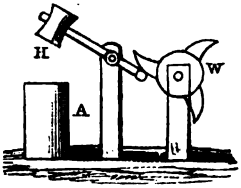

Fig. 75.

The lever *ac*, fig. 76, will rise and fall through a space equal to *ab* during the revolution of the heart-shaped wheel or camb, the centre of which is *b*.

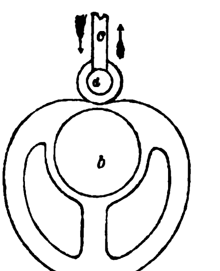

Fig. 76.

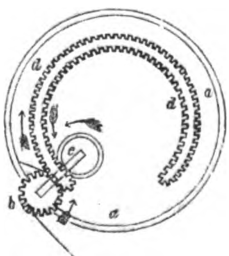

Fig. 77.

An alternate motion from one side to another is given to a drum, or horizontal drum or pulley, *aa*, fig. 77, by the contrivance known as the *mangle-wheel motion.* To the face of the pulley a double circular rack, *dd*, is attached; the axis of the pinion *b*, which gears into this rack, is allowed to traverse in a slot, so that it will, on reaching the end of the outside rack, pass round the teeth of the curved ends, along the slot, and gear with the teeth of the inside rack. By giving a continuous motion to the pinion *b*, it will engage with—say the teeth of the outside rack—thus moving the rack and pulley in the opposite direction; but as soon as the pinion gears with the teeth of the inside rack, the direction of both is the same (see the annular-wheel, fig. 69); and the pulley thus moves in an opposite direction.

To change Reciprocating into Circular Motion.—By the crank. The reciprocating movement of the piston-rod —the parallelism of which is preserved by the cross-head sliding between the guides—is changed into the circular one of the fly-wheel by the crank fixed to the fly-wheel shaft and the connecting-rod. To admit of the movement of the rod from right to left, and *vice versâ*, it is jointed to the crank-pin at one end, and to the piston-rod cross-head at the other. An exemplification of this will be found in the crank overhead-engine in the paper on the STEAM-ENGINE. The continuous circular motion of the fly-wheel of a knife-grinder's wheel is produced from the alternate rising and falling of the foot of the operator, acting on the footboard by the intervention of the connecting-rod and crank. The sun-and-planet wheel motion was used by Watt to change the reciprocating motion of the piston-rod into the circular one of the fly-wheel. To the end of the connecting-rod a toothed wheel was firmly fixed; this geared with another wheel of the same size, fixed on the fly-wheel shaft; the centres being connected with a jointed link. The connecting-rod, as it rose and fell, carried the wheel at its extremity round the periphery of the wheel fixed on the fly-wheel shaft, and at the same time gave motion to it and the fly-wheel.

To change a Circular into a Reciprocating Motion.—A very general method of doing this is by the use of the eccentric, the constructive details of which we have shewn in fig. 67.

An *eccentric-wheel* is a wheel with an axis not in its centre, but at a point nearer one side than the other. Fig. 78 represents the action of a wheel of this kind. W is the wheel, and A the axis upon which it is fixed. When the axis turns, the wheel turns with it. As the axis never moves out of its place, the wheel necessarily describes a path of gradual rising and falling in its revolutions. Suppose an object, as T, pressing upon the upper edge of the wheel, so as to accommodate itself to the motion, it is obvious that, by the action of the wheel, this object will be alternately raised and allowed to fall. Or suppose that a rod is hung from a point of the wheel near where T rests, it is similarly obvious that the rod would be raised or depressed according as the wheel turned. Thus, a rising and falling motion may be effected by an eccentric-wheel.

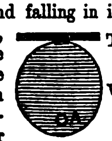

Fig. 78.

The heart-shaped wheel or eccentric *b*, fig. 76, is another method of producing reciprocating from circular motion; as also the rack and pinion, fig. 73.

To change a Reciprocating Circular Motion into a Reciprocating Rectilineal.—The well-known parallel motion of Watt is a familiar exemplification of this movement.

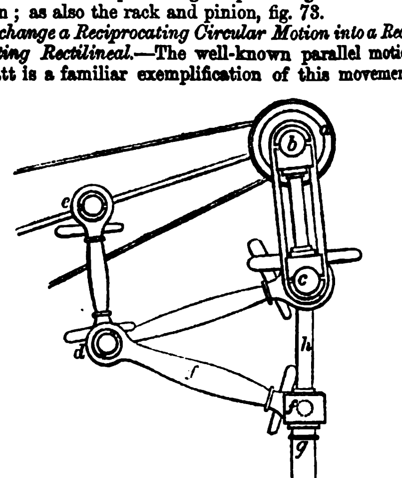

Fig. 79.

Let *ea*, fig. 79, be the beam; to two studs or centres in the direction of its length, two links of equal length are jointed at one end, as *be*, and at the other to another link *cd*, which is always parallel to the line of centre of *ea*. A lever, *f*, is jointed at *d* at one end, and at the other to a stud on a fixed support *g*. The end of the piston-rod, *h*, is fixed to a cross-head or bar jointed with the ends of the lever *cb*. On the other side of the beam a similar set of levers are arranged. The piston-rod *h*, in this arrangement, moves in a straight line, while the

end of the beam, *ea*, moves in the arc of a circle.—A continuous circular motion is changed into a reciprocating rectilineal one by the contrivance known as *White's parallel motion*. This is illustrated in fig. 69, and proceeds upon the principle, that if a pinion *b*, of diameter equal to the radius of the annular-wheel, *aa*, be made to roll within the fixed annular-wheel, a point *c*, in the pitch circle of the pinion *b*, will describe a right line. If, then, the end of a piston-rod be attached to this point, it will move in a straight line.

Accumulating and Equalising of Power.—Power is susceptible of *accumulation*—that is, of increasing little by little—and of being expended either gradually or in one or more violent efforts; the efforts being entirely the concentrated amount of the previous accumulation.

In consequence of this convenient accumulation of power in machines, plans have been devised for establishing *reservoirs of power*, as they may be called, in connection with moving machinery.

In contrivances in the arts, power is sometimes accumulated in order to be given out in the form of a rapid and effective blow. This may be done by means of a horizontal bar or lever, poised on a central axis, and loaded at each end with a heavy ball of lead or iron. After communicating to the machine a sufficient power of rotation, it will proceed with an enormous accumulated energy and momentum, till it expend its force either by friction in turning, or upon some fixed obstacle presented to it.

The press used for stamping or taking impressions of coins and similar articles from dies, furnishes one of the best examples of the instantaneous expenditure of accumulated power. A press of this kind is represented in fig. 80.

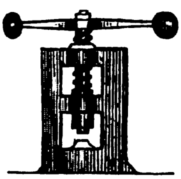

Fig. 80.

In most machines, both the moving force and the resistance to be overcome are liable to fluctuations of intensity at different times during the operation of working.

The irregularities in the motion of machinery, from whatever cause they arise, are remedied by giving to each machine a *reservoir of power*, from which force may be given at all times to equalise the motion, according as it may be required. These reservoirs of power are usually in the form of *fly-wheels*.

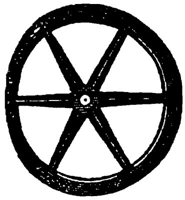

Fig. 81.

A fly-wheel is generally made of iron, and consists of a heavy rim or circumference, joined to a central axis by cross-bars or spokes (fig. 81). In most cases, it is placed in close connection with the first moving force, the effect of which it equalises in its passage to the machine.

Regulation of Power.—In some mechanical contrivances, the force which is applied varies in its intensity, while the wheels of the machinery require to be kept at a uniform speed. This is generally the case when the force is communicated from a steel spring, which, after being wound up, is suffered to relax. Fig. 82 is a spring suited for operations of this kind. It is represented in a state of relaxation, and is wound up into a compact form by means of a spindle fixed to its inner extremity.

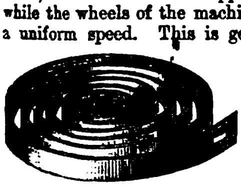

Fig. 82.

The force communicated by the relaxing of the spring varies in its intensity. The force is greatest when it begins to relax, and it gradually weakens till its expansive energy is exhausted. To compensate this defect, a very ingenious plan is adopted, and which is put in operation in the apparatus of the common watch.—

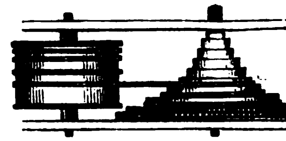

Fig. 83.

Fig. 83 represents the apparatus of motion in a watch, somewhat magnified.

In proportion as the intensity of the force weakens, and the barrel takes off the chain from the fusee, and winds it about itself, so does the chain act upon a longer lever, or so does it gain a greater lever-advantage, by drawing at a wider part of the cone. Thus the gradual loss of force is counterbalanced by a gradual increase of lever-advantage. (The case resembles that of a strong man working with a short lever, and a weak man working with a long lever; both are equal in effect in balancing any resistance.) The wheel-work of the watch is moved by teeth on the lower circumference of the cone.

The steam-engine governor is another method of regulating the speed of a machine.

Engaging and Disengaging Machinery.—The most common and simplest device used in cases of motion by belts, consists in having a *fast* and *loose pulley*. Alongside of the pulley whose axle moves the machinery, and on which the belt works, there is a pulley or wheel loose on its axle, called the loose-pulley, from its inoperative character. When the machine is to be stopped, the belt is shifted from the fast or active pulley to this loose-pulley, which it turns without producing any effect on the machinery. Motion is restored to the machine by shifting the belt back to the fast-pulley. A long rod, with a clutch at its extremity, and easily affected by the hand of the workman, turns the belt off or on at a moment's notice.

Another method of engaging and disengaging machines is by the use of the sliding-clutch, or coupling. Let *a*,

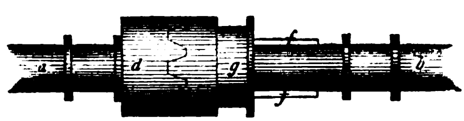

Fig. 84.

fig. 84, be the driven shaft, or that which takes the motion to the machine; and *b* the driving-shaft. To *a* a coupling-box is fixed, with projections and indentations on its face; a clutch, with corresponding indentations, &c., is capable of sliding along the shaft *b*, on two feathers or ribs projecting from its surface, but which revolves with the shaft. This clutch is moved to and from the fixed clutch *d* by a lever, the fork of which embraces the journal *g* of the clutch *dg*. When the clutch *d*, which is carried round by the shaft *b*, is moved along the feathers, so that its projections go into the indentations of the clutch *g*, and the two become locked together, the shaft *a* partakes of the motion of *b*. The two are kept in contact by the lever which moves *g* being placed against a stud; by releasing it from this stud, the lever can be moved, and the clutch *g* thrown out of connection with *d*, and the motion of *a* thus stopped.

OBSTACLES TO MOTION.

Moving bodies, as machines and wheel-carriages, are less or more retarded in their velocity by friction, and the resistance of the atmosphere, while vessels moving on water are retarded by the resistance both of the atmosphere and of the liquid in which they are buoyant.

Friction.

Friction is an effect of the action of rubbing of bodies one upon another.

This effect is produced by inequalities of surface. No such thing is found as perfect smoothness of surface in bodies. In every case there is, to a lesser or greater extent, a roughness or unevenness of the parts of the surface, arising from peculiar texture, porosity, and other causes; and therefore when two surfaces come together, the prominent parts of the one fall into the hollow parts of the other. This tends to prevent or retard motion. In dragging the one body over the other, an exertion must be used to lift the prominences over the parts which oppose them, and this exertion is similar to that of lifting or drawing of bodies up inclined planes, or over upright protuberances. The effect so caused is called *friction*.

Friction acts as a retarding influence in the action of all mechanical contrivances, and a due allowance must in every case be made for it. In many instances, it destroys more than a half of the power employed, and seldom destroys less than a third. This latter is the usual allowance made in calculating machine labour.

The action in overcoming friction being of the nature of lifting or drawing of bodies up inclined planes, gravity is permitted to have an effect in the drawing of bodies upon horizontal planes not perfectly smooth. Thus *weight* forms an important element in calculating the probable amount of friction of a body.

Friction is found to depend on the following circumstances:—*1st*, The degree of roughness of the surfaces. *2d*, The weight of the body to be moved. *3d*, The extent of surfaces in certain bodies presented to the action of friction. *4th*, The nature of the bodies. *5th*, The degree of velocity of the motion. *6th*, The manner of the motion.

Roughness.—It is of the utmost importance to smooth the surfaces. An apparently insignificant piece of matter, or even particles of dust, will greatly retard the motion of a body.

Weight.—Friction always increases in exact proportion as the weight increases, when all other circumstances remain the same. Any moving part of machinery, therefore, should be made as light as possible, consistent with strength and durability.

Extent of Surfaces.—Rough bodies are more easily drawn along when their surface of contact is narrow than when they are broad. For example, it is easier to draw two narrow brushes across each other than two broad ones of the same weight. Friction may therefore be diminished in rough bodies by lessening the extent of surfaces in contact. But there is a limit to this diminution. If the moving surface be very thin, and the other surface soft, the thin surface will plough a groove in the soft one, and thus the friction will be increased, and the machine injured. In the case of smooth hard bodies, extent of surface makes little difference in the friction.

Nature of Bodies.—It is a remarkable truth, that two bodies which are of the same nature, or homogeneous, produce greater friction in movement than bodies which are different in their nature, or heterogeneous. This arises from the natural cohesiveness of particles of the same material. Thus, iron working against iron, steel against steel, or brass against brass, causes in each case greater friction and wearing of parts than when iron or steel is made to work against brass. This circumstance is always attended to in the construction of machinery.

Degree of Velocity.—Friction is a uniformly retarding force, except in the case of small velocities, when it is greater in proportion. The reason of its being greater in small velocities is, that in these cases time is allowed for the prominences of the moving body to sink deeply into the hollows of the surface on which it is moving, which has a retarding effect.

Manner of the Motion.—The least advantageous manner in which one body can be moved upon another, is to cause it to slide or drag. The most advantageous manner is to cause it to roll or turn. The causing of a body to roll instead of to slide, is one of the chief means of diminishing friction.

Various plans have been tried to modify the friction of wheels in their sockets. One remedy consists in constantly keeping up a fresh lubrication from small reservoirs of oil placed in the axles or gudgeons, and which supply the deficiency as it occurs. A more effectual plan consists in surrounding the inner sides of the gudgeons with small wheels, upon the rims of which wheels the axle works in turning. These *friction-wheels*, as they are called, save the axle from rubbing on the inner surface of the gudgeons, and transfer the friction to their own small axles.

Uses of Friction.—Whatever may be the retarding and frequently inconvenient effects of friction in reference to the action of mechanism, it is certain that friction is indispensable in the economy of both nature and art. It is a property which is frequently necessary in order to allow one kind of matter to possess a hold upon another without actual cohesion. One familiar use of friction is felt when we attempt to walk on ice. In order to keep our feet from sliding when on ice, if we received any impulse, we either tie rough substances on our shoes, or scatter ashes in our path, and thus we receive the benefit of friction. It is by friction that rains wear down hills, and that rivers wear away their banks, by which ceaseless process the external configuration of the globe is constantly undergoing a change. The operations in art of washing, cleaning, scouring, sharpening, polishing, cutting, bruising, beating, and so forth, are all effected less or more by friction. The hold which one fibrous substance has on another, or mutual friction, permits the operations of weaving cloth, twisting ropes and threads, and the tying of one body to another. Thus friction is of universal service; and the only known instances in nature in which it is not required, and therefore not present, are the movements of the heavenly bodies, which, so far as has been determined, revolve in a vacuum, and are consequently not impeded in their motions.

Resistance of Air and Water.

Atmospheric air and water are fluids of different densities, but both present an obstacle to the motion of solid bodies through them.

There is a rule in respect to the resistance presented in moderate velocities which applies both to air and water: it is, that *the resistance is proportional to the square of the velocity*. For example, a velocity of twenty miles an hour causes a resistance four times greater than a velocity of ten miles an hour; for the square of twenty—which is 20 times 20, or 400—is four times the square of ten—which is 10 times 10, or 100. Thus, by increasing the velocity of bodies through the air or water, we must increase the power in a greater proportion, in order to compensate the loss caused by resistance.

Resistance to motion in fluids is greatly modified also by the form of the moving body. The form that gives least resistance is nearly that of a parabola, or a form somewhat resembling the breast of a duck, the head of a fish, or the rounded bow of a vessel, sharpened to cleave the fluid through which the body passes. The body should also taper backwards, like the body of a fish.

For a classification of the different machines in use, the sources of moving power, and a description of the method of estimating their power, see the number on MECHANICAL ENGINEERING.

HYDROSTATICS—HYDRAULICS—PNEUMATICS.

MANY important properties of bodies depend upon the form or state in which they exist. Thus the properties treated of under Mechanics are such as arise chiefly from the *solid* state of bodies. But consequences, scarcely less important, arise from the other two forms in which matter presents itself—from the *liquid* condition of water, for instance, and the *gaseous* or aëriform condition of air; and these form the subjects of the present treatise.

All matter that we are acquainted with presents itself in one or other of the three forms mentioned; and the same substance may generally be made to assume them all in succession. Thus liquid water may become solid ice, or aëriform steam. These different *states of aggregation*, as they are called, depend upon the way in which the particles, or molecules, are united. From the fact that a force is required to separate the parts of a solid body, it is inferred that an attractive force is at work drawing or holding them together—the attraction of *cohesion*. From the fact, again, that force is necessary to restrain the molecules of a gas from separating further than they are, it is inferred that a repulsive force is at work among them. Attractions and repulsions, thus acting between the ultimate molecules of bodies, are called *molecular forces*. Since the same body can generally exist both as a solid and as a gas, it is assumed that both forces are inherent in the molecules of all substances. When the attractive force preponderates, the solid state is the result; when repulsion preponderates, the gaseous state results; an equilibrium of the two forces produces a liquid.

Liquids and gases agree in this, that their particles seem at liberty to glide about among one another without friction; they *flow*, and hence both classes of bodies are called *fluids*. There are all degrees of fluidity. Some fluids are thick and viscid—such as tar, honey, and some metals in a state of fusion. Viscid fluids are in general not homogeneous; they consist of solid granules floating in a real fluid. Alcohol and ether are more fluid than even water. The most perfect fluidity belongs to the gases.

But what chiefly distinguishes gases from liquids, is elasticity. A cubic foot of any gas may readily be compressed into half a foot; double the pressure will reduce it to a quarter of a foot; and when the pressure is removed, the gas returns to its original bulk. But no ordinary pressure produces any sensible compression on water or any other liquid. Hence gases have been denominated *elastic fluids*, and liquids *non-elastic*. It is on account of this difference that the mechanical properties of the two classes of fluids are treated of apart. The laws of liquids form the subject of Hydrostatics and Hydraulics—the former term (from two Greek words signifying *water* and to *stand*) embracing the doctrine of the equilibrium of liquids; the latter (from the Greek for *water* and a *pipe*), the doctrine of liquids in motion.

We have said that liquids cannot be sensibly compressed by any ordinary force; and this is so far true, that both in the theory of hydrostatics and in practice they are assumed to be perfectly incompressible. But the assumption is not absolutely correct. They are slightly compressible under great pressure. By sinking a vessel in the ocean to the depth of 6000 feet, where every square inch supports a weight of 2648 pounds, it is found that twenty cubic inches of water contained in the vessel are reduced to nineteen cubic inches, or the volume of water is diminished by one-twentieth. A pressure equal to that of the atmosphere, or fifteen pounds on the square inch, reduces a million cubic inches of water to about forty-five inches less.

HYDROSTATICS.

In treating of the mechanical properties of liquids, water, as the most common and important, is taken to represent the whole class. We have nothing to do here with the fact that water is composed of two gases—that belongs to chemistry. The atoms of oxygen and hydrogen having united in pairs to form compound atoms or molecules of water, the science of Hydrostatics depends on the way in which these compound molecules, or particles, join together to form a mass. It is obviously different from the way in which a heap of sand is composed. For one thing, the sand, however fine, may still be seen to be composed of separate solid grains, which, under the microscope, become real blocks of stone, while the molecules of water are quite invisible, and must be inconceivably minute. The particles of sand, again, move over one another, it is true, but with considerable friction or resistance, as is seen by their remaining standing up in a heap; the particles of water slide upon one another without the least apparent friction, and when not confined, spread out into a thin film. Another point of difference is, that the separate particles of sand have no cohesion among themselves; the cohesion among the molecules of water, though weak, is still sensible, as is seen in a drop hanging suspended at the end of a rod. A liquid differs from a solid, not so much in the force with which the particles of either resist separation, as in the force with which the particles of the solid resist changing their relative position. We may conceive two molecules of water, in the form of two minute balls, in contact; and when one of them is pushed, it slides round on the other, adhering to it as it moves. Two molecules of a solid resist this sliding motion, and if forced to change their points of contact, can no longer cohere; as if they only attracted each other by certain sides. It is this property that enables solids to retain a fixed shape; fluids have no shape, but what they receive from the containing vessel.

Not only have the particles of a liquid an attraction for one another—the attraction of *cohesion*—but there is an attraction between most liquids and solids; this is the cause of a liquid *wetting* a solid. The particles of one liquid, also, often adhere to those of another; and gases similarly adhere to liquids. This species of attraction is known as *adhesion*. The combined action of *adhesion* and *cohesion* gives rise to many interesting phenomena; among others, to *capillary* attraction and *osmose*, described among the general properties of matter under NATURAL PHILOSOPHY.

It is the perfect *mobility* of the particles of liquids that gives them the mechanical properties considered in Hydrostatics. The fundamental property may be thus stated: *When a pressure is exerted on any part of the surface of a liquid, that pressure is transmitted undiminished to all parts of the mass, and in all directions.* Most of the other propositions of hydrostatics are only different forms or direct consequences of this truth.

The proposition may be experimentally proved in a variety of ways. If, for instance, a bladder is filled with water, and tied, and then pressed down with one hand; the other hand, if applied to the bladder, will be pushed out with corresponding force, and that

whether resting on the top, the sides, or under. Suppose, again, a close box B filled with water, and having a tube inserted into the upper cover with a plug or piston *a*, an inch in area, fitting into it. If the piston *a* is now pressed down upon the water with a force equal to a pound-weight, the water, being unable to escape, will react upon the piston with the same force; but it obviously will not press more against *a* than against any other part of the box, therefore every square inch is pressed outward with the force of a pound. If, then, there is another tube inserted in any part of the box with a plug of the same area, as at *b*, it will require a force of a pound to keep this plug in its place. (We leave out of account at present the pressure upon *b* arising from the *weight* of the water in the box above it, and consider only the pressure propagated by the forcing down of the plug *a*.) However many plugs of the same size there were, each would be pressed out with the same force of a pound; and if there were a large plug of four times the area, as at *c*, it would be pressed out with a force of four pounds.

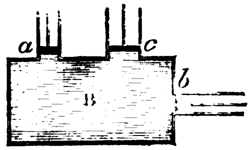

Fig. 1.

We have only, then, to enlarge the area of the piston *c* to obtain any multiplication of the force exerted at *a*. If the area of *c* is 1000 inches, that of *a* being one inch, a pressure of one pound on *a* becomes a pressure of 1000 pounds on *c*; and if we make the pressure on *a* one ton, that on *c* will be 1000 tons. This seemingly wonderful multiplication of power has received the name of the *hydrostatic paradox*. It is, however, nothing more than what takes place in the lever, when one pound on the long arm is made to balance 100 pounds on the short arm. The law of virtual velocities holds in the one case as well as in the other: when we think of the machine in motion, we see that what is gained in power, is lost in time. If the piston *a* descend one inch, it will raise the piston *c* only the one-thousandth part of an inch. It is on the principle now explained with regard to the two pistons *a* and *c*, that the very useful machine called *Bramah's* Press is constructed, as will be more fully described afterwards.

If the pressure we have supposed exerted on the piston *a* arose from a pound of water poured into the tube above it, it would continue the same though the piston were removed. The pound of water in the tube is then pressing with its whole weight on every square inch of the inner surface of the box—downwards, sidewise, and upwards—and, if the box is twenty inches each way, so as to have upwards of 2000 inches of surface, this one pound of water is tending to burst it with a force of about a ton. That this is no mere theory, may be proved without much difficulty, by fitting a long small tube, *b*, into the top of a cask, *a*, as represented in fig. 2. If the tube is only the twentieth of an inch in area, and is made long enough to contain a pound of water, it gives a bursting force of twenty pounds on every square inch of the inner surface—a strain which no ordinary cask could resist.

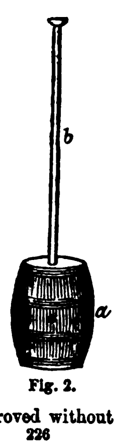

Fig. 2.

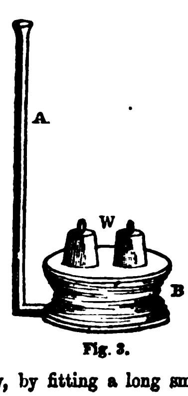

Fig. 3.

The apparatus called the *hydrostatic bellows* acts on the same principle (see fig. 3). It consists of two stout circular boards connected together by leather in the manner of a bellows B. The tube A is connected with the interior; and a person standing on the upper board, and pouring water into the tube, may lift himself up. If the area of the upper board is 1000 times that of the tube, an ounce of water in the tube will support 1000 ounces at W.

If we conceive a mountain having a cavity in its interior, as at B in fig. 4, without any outlet except a crevice, A, extending upwards to the surface; the rain descending and filling the crevice to a great height, might be sufficient to burst the mountain asunder.

Fig. 4.

PRESSURE OF WATER ARISING FROM ITS OWN WEIGHT.

Water has weight like solids, and this weight produces pressure, but the quality by which it transmits pressure in all directions makes its weight be felt in many respects differently from that of solids. Thus, suppose a cylindrical vessel filled with a piece of ice exactly fitting it; the whole weight of the ice will rest on the bottom, the sides being unaffected. But if the ice is now melted, the bottom will sustain the same weight as before, and the sides will at the same time be pressed outwards with a certain force. Any object immersed in water is also pressed or squeezed by the weight of the water. We have now to determine the amount of this pressure caused by the weight of water in various circumstances.

The pressure of water increases in intensity with the depth, without regard to the shape or size of the vessel containing it. Suppose the water in the two vessels represented in fig. 5 to be divided into layers of an inch deep. If the area of the tube C is one square inch, and that of the larger cylinder, A, ten inches, the top layer in the tube will contain a cubic inch of water, and that in the cylinder ten cubic inches. Now, these layers rest on the surfaces of the layers below them; the second layer in the tube sustains the weight of a cubic inch of water; that in the cylinder, ten cubic inches. But in the last case the weight is equally distributed over ten square inches of surface; in both cases, then, the pressure on a square inch of the upper surface of the second layer is the weight of a cubic inch of water, or about 252 grains. And this pressure is not merely downwards. The film of particles sustaining this weight react on the upper layer, pushing it upwards, and also push sidewise

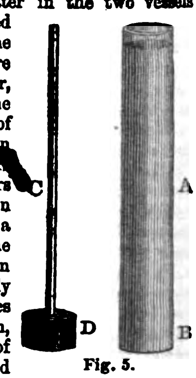

Fig. 5.

against each other and against the sides of the vessels, all with equal force. In like manner, each square inch of the surface of the second layer, in either vessel, has to bear the weight of two cubic inches of water, and the particles at that depth push upwards and laterally with corresponding intensity. The pressure thus increases with the depth equally in the narrow vessel and in the wide.

If we suppose the vessels to be each a foot deep, it is evident that on every square inch of the bottom of the cylinder there will rest a pile of twelve cubic inches (weighing about half a pound troy), and therefore the pressure on the whole bottom will be the weight of ten such columns. But from the shape of the other vessel, the lower part of which is enlarged, it is not so evident what the pressure on the bottom is. One thing is clear, that, on the square inch in the middle of the bottom immediately under the tube, there rests a column of twelve cubic inches. Now, there must be the same pressure among the particles of the water lying around the bottom of this column, as among its own particles, otherwise there would be a flow towards the part where the pressure was less. Throughout the whole of the enlarged space D, there is the same pressure as there is at the same level immediately under the tube. Therefore, if the enlarged part of the vessel is of the same width as the cylinder, having an area of ten square inches, the pressure on the whole bottom is equal to the weight of ten times twelve cubic inches of water, exactly as in the cylinder at B.

It thus appears that *the pressure on the horizontal bottom of a vessel is as the area of the bottom and the perpendicular height of the liquid*, and that without regard to the shape of the vessel.

Take the case of two vessels of equal capacity, and shaped as in figs. 6 and 7. In fig. 6, the bottom is pressed with the weight of the column of water ACDB. In fig. 7, the portion CD, equal to the whole base of the other, sustains an equal column; but from the law of liquids the same pressure is extended over the whole bottom. Now, if the diameter EF is three times the diameter CD, the larger bottom is nine times the area of the smaller. Therefore the pressure on the bottom of fig. 7 is nine times the pressure on that of fig. 6, although both vessels contain the same quantity of water. If the bottoms of the vessels were separate from the sides, and kept in their places by springs or weights, it could be shewn experimentally that such is the case.

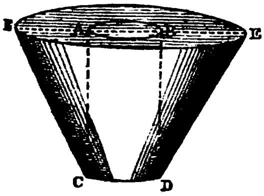

Fig. 6.

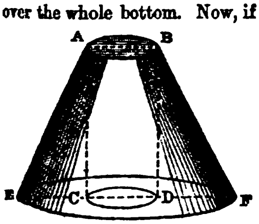

Fig. 7.

A strange consequence would seem to follow from this. If the two vessels in fig. 5 were placed on the opposite scales of a beam, the bottoms of both being equally pressed, it would seem as if they must balance each other. Similarly, we might expect fig. 7 to weigh nine times as much as fig. 6. But that such cannot be the case appears from the following considerations:—In the upright cylinder in fig. 5, the lateral pressure being directly horizontal, neither presses the sides down upon the bottom nor lifts them up; but with the irregular vessel it is different. Where the small tube C enters the wide part D—say two inches from the bottom—the pressure of the column is equal to ten cubic inches of water on the square inch; and as this pressure acts upwards as well as downwards, the horizontal cover of the wide part is pressed *upwards* with a force of ten cubic inches on the square inch. Its area, the tube being one inch, is nine inches, so that the whole upward pressure is 9×10 cubic inches. The cover being attached to the sides, and the sides to the bottom, a part of the pressure on the bottom is thus counteracted, and only the difference—the difference between 10×12 and 9×10—or thirty cubic inches of water—remains to weigh down the scale. The confined water is in this case like a person in a covered box who should place his shoulders against the top and press against the bottom with his feet; he would thus add nothing to the weight of the box beyond his own dead weight.

Pressure of Liquids on the Sides of Vessels.—We may arrive at a rule for calculating the amount of the lateral pressure of liquids by considering a vessel of the shape represented in the annexed figure. Dividing the depth into ten equal sections, representing feet, conceive the water composed of horizontal layers, each a foot thick. Then on a square inch of the surface of the second layer, adjoining the side, there rests a pile of twelve cubic inches pressing it with their weight. But liquids press sidewise as well as downwards; and therefore the pressure against the side, just where the first and second layers meet, is at the rate of the weight of twelve cubic inches on a square inch. At the second section, the pressure is evidently double, or that due to twenty-four inches, and so on to the bottom, where a square inch sustains the pressure of ten times twelve cubic inches of water. If, then, we take a vertical row of square inches, or—which is the same thing—of square feet, on the side of the vessel, they sustain pressures diminishing in intensity from the bottom to the top; and to get the amount of pressure on the whole, we must multiply the number of square feet by the *mean* pressure, which is at section 5, and amounts to the weight of five cubic feet on every square foot.

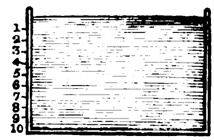

Fig. 8.

We may thus calculate the degree of lateral pressure in vessels having perpendicular sides *by first finding the number of square feet in the sides below the surface of the liquid, and then multiplying that by the number of feet in half the depth of the liquid.* The number of square feet in the sides is found by multiplying the number of feet in the circumference of the bottom by the number of feet in the depth of the liquid.

The above rule gives the pressure in cubic feet of water. It is easy to reduce this to weight by remembering that a cubic foot of water weighs very nearly 1000 ounces (strictly 997 ounces). *Example.*—Suppose a vat 24 feet deep from the surface of the liquid, and 40 feet in circumference. The area of the sides is $24 \times 40 = 960$; 960 multiplied by half the depth, or 12, gives 11,520 cubic feet of water; and 11,520 cubic feet of water weigh 11,520,000 ounces, or upwards of 320 tons—the bursting force which the hoops of the vat have to resist.

The same principle holds though the sides be not perpendicular, but sloping outwards or inwards. The rule is still—multiply the number of square feet in the side by half the perpendicular depth of the liquid; or rather, if the side is not rectangular, by the average depth of the liquid upon the side—that is, by the depth of the centre of gravity of the side.

It is easy to see that the pressure on the sides of a vessel may often, in this way, be greater than the whole weight of the liquid, according to the shape of the vessel. In a cubical box, in which any side is equal to the base, the pressure on one side is equal to half the weight of the contained water; and on all four sides it is just double the weight. When the area of the upright surface pressed upon is twice the area of the bottom, the lateral and perpendicular pressures are equal.

The circumstance of pressure increasing in proportion

to depth, makes it necessary to increase the breadth of embankments for dams and canals from the top downwards; also to increase the strength of the lower hoops of large vats, to prevent their bursting. It likewise teaches the propriety of making dams, ponds, canals, and vessels for liquids generally, as shallow as is consistent with convenience or their required purpose. In every case, it is important to recollect that the degree of pressure on the sides is irrespective of shape or size of the contents, and depends exclusively on the perpendicular depth of the liquid.

When the poet speaks of 'the *broad* ocean leaning against the land,' we are apt to think of the broadness as adding to the weight that the land has to sustain. But the pressure against a square foot of the shore of the broad Atlantic is no greater than against a foot of the shore opposite Dover, or a foot of the side of a canal, at the same depth. The pressure against the gates of a canal is the same whether the next lock is a mile or whether it is fifty yards off. It might be brought within a foot, or even a fraction of an inch, and the weight on the gate would remain unchanged so long as the depth was the same. This being the case, it is really no more difficult to embank the calm ocean than a small lake of the same depth; except for the violence of the waves, the same strength of dike would resist the weight in both cases.

When we consider that every five feet in depth gives a weight of about two pounds on the square inch, we see what an enormous compression bodies must suffer when sunk to great depths in the ocean. This of itself would put a limit to the depth at which fishes can live.

THE LEVEL SURFACE OF LIQUIDS.

A horizontal plane or horizontal line is one that is perpendicular to, or right across the direction of a plumb-line, or the direction of gravity. The surface of a mass of water, if not extensive, does not differ sensibly from such a plane. This follows from the properties of liquids above considered. Suppose a horizontal plane at any depth in a mass of liquid; if any part of the surface were heaped up, so as to stand higher above this level than other parts, there would be more pressure at the bottom of the column under that part than elsewhere in the same horizontal stratum, and a flow would take place till the higher column were of the same depth as the others. Or we might consider the particles at the surface of such a liquid heap as lying on an inclined plane, when their gravity would make them roll down to a lower position. It is only the imperfect mobility of sand that prevents it from assuming a perfectly level surface, as well as water.

It seems so natural that the surface of an unbroken mass of liquid should be all of one height, that we seldom think of it as requiring explanation. But when the surface of a liquid is not continuous, being contained in separate vessels with communication between them, it requires consideration and experience to convince us that the several parts of the surface must in all cases stand at the same level. A common tea-pot affords the most familiar illustration of this truth. Since pressure in a liquid depends exclusively on the depth, without regard to the shape or size of the mass, the pressure on a square inch at the level of communication is the same under A as under B; thus there is equilibrium. If an inch of additional water is put on the top at B, the pressure at the bottom is increased by that much, and a flow takes place along the line of communication till the whole again stand at the same height, the surfaces coinciding with a horizontal line AB.

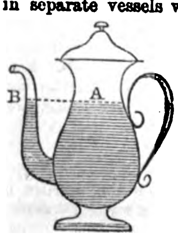

Fig. 9.

We have considered the surface of water as perfectly flat and straight; and a small surface is practically so. But in the case of extensive surfaces—such as that of the ocean or of a large lake—it becomes evident that the shape is round or spherical, partaking of the general form of the earth. By considering the figure below, we shall see that a liquid must assume this shape. The curve ETS represents a portion of the earth's surface, the centre being C. At any point T, the plumb-line PT, or the direction of gravity, is towards the centre. A line perpendicular to this is a horizontal line; and if such a line, or a flat plane, were extended far enough, it would rise up from the surface of the earth like TL, forming what is called a *tangent*. If particles of water were lying on such a plane at T, the force of gravity would press them right against the plane, and they would have no tendency to flow to either side. But water at L is differently circumstanced. Gravity does not press it right against the plane, but slanting, towards C, and thus gives it a motion along the plane to T. The water is, in fact, on an inclined plane all the way till it get to T, and will flow in that direction till it heap up the surface into a round shape, where every point is equally distant from the earth's centre.

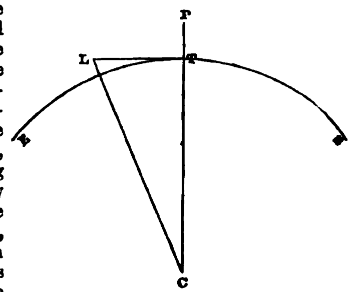

Fig. 10.

It is only when a sheet of water is stretched out to an extent of several miles that the convexity becomes conspicuous. It is very perceptible on the ocean when a ship is approaching on the horizon; first the masts and sails of the ship are seen, and lastly, the hull. The convexity of the land is not so conspicuous, in consequence of the many risings and fallings in the surface. It is only in extensive plains that the roundness can be perceived in the same manner as at sea.

The amount of the earth's convexity can be calculated exactly. It is very nearly eight inches in each mile; that is, if TL (fig. 10) is a mile long, the point L will be eight inches above the surface.

In constructing canals and railways, allowance must be made for the convexity of the earth; for the channel of a canal, or a line of level railway, does not form a straight line, but a curve; it is not a part of the tangent or *apparent level* TL, but of the curve TE, which is the *natural or dead level*. The instrument by which levels are determined is called a *spirit-level*. It consists of a glass cylinder *ac*, filled with spirits all except a small space. It is placed for protection in a wooden case, the bottom of which is exactly parallel with the sides of the tube. If the instrument is laid on the upper surface of a stone slab or a beam, and if one end of the beam is higher than the other, the liquid in the tube will seek the lowest position, and the air-bubble will move towards the higher end; when the bubble rests in the middle, as at *b*, the surface is horizontal or level. To ascertain levels at a distance, the spirit-level is fixed below a small telescope, the tube of the telescope and the glass tube being made exactly parallel. The telescope being fixed on a stand, is adjusted by screws until the air-bubble of the spirit-level stands exactly in the middle, and is thus made perfectly horizontal. A pole being now set up at the spot where the level is to be found, the level telescope is directed to it, and the point of the pole which appears in the centre of view is in a horizontal

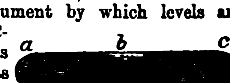

Fig. 11.

line with the eye. If the distance is short, this point may be considered as the level; but if the pole is as far as a mile off, the natural level at which water would stand, if there were a sheet of it all the way, will be eight inches below.

SOLIDS IMMERSED IN LIQUIDS.

When a solid is immersed in a liquid, it displaces exactly its own bulk of the liquid. This requires no demonstration; as soon as we conceive clearly what is meant, the truth of the proposition is self-evident. Of course it is only of solids that are neither melted nor penetrated by the liquid that the proposition holds good.

If a cubic inch of wood or of a metal is wholly immersed in a vessel previously full of water, the liquid that occupied the space where the solid now is, must overflow; or, if the vessel was not full, the level of the liquid must rise. This affords a ready means of measuring solids, even the most irregular in shape. To ascertain what bulk of solid metal there is in a gold chain: have a cylindrical vessel with a base of known area—say a square inch—filled to a certain height with water; drop in the chain, and note the rise of the liquid. If it rise an inch, the chain contains a solid inch of gold, and so for any fraction of an inch. Archimedes is said to have been the first to think of measuring solid bodies in this way, and to have applied it in detecting the adulteration of a gold crown.

Every one must have experienced that a heavy body held in the hand becomes lighter when it is immersed in a liquid. We have now to consider how this loss of weight arises, and what is its amount.

Let a solid AB occupy a space within a mass of water.

Fig. 12.

Conceive first, that the space were again occupied by a body of water separated from the rest by an imaginary film; this water will clearly remain suspended like any other portion of the mass. Now, as its weight is pressing it downwards, there must be an equal force acting upon it upwards. That force arises from the pressure of the surrounding liquid, which is acting upon it in all directions, upwards, downwards, and laterally. Some parts of this pressure counteract other parts; but the under surface being at a greater depth than the upper, there remains a balance of upward pressure. This balance or result must be exactly equal to the weight of the conceived isolated body, and must also act on the centre of gravity of that body *g*, otherwise it could not keep it at rest. The upward pressure, then, on any separate portion AB, say a cubic foot, within a mass of liquid, is equal to the weight of that portion. If we now suppose the mass of water, AB, to become solid ice without change of bulk, the same pressure will act upon it as before; and if we further conceive the cubic foot of ice to become a cubic foot of gold, the upward pressure upon it will remain the same—namely, the weight of a cubic foot of water, or the weight of the water it displaces. To this extent the water supports it, and renders it lighter.

It appears, then, that *a solid body in a liquid loses as much weight as an equal bulk of the liquid weighs.* If a cubic foot of the liquid and of the solid have equal weights, the solid will lose all its weight, or will remain in the liquid wherever it is put; if a cubic foot of the liquid weigh more than one of the solid, the solid will not only lose all its weight, but will rise up, and that with a force equal to the difference; if a cubic foot of the liquid weigh less than one of the solid, the solid will lose weight, but will still sink.

When a solid swims, or rises and *floats* on the surface of a liquid, the next problem of hydrostatics is to determine how much of it will be below the surface. We have already seen that any solid in a liquid is pressed upward with a force equal to the weight of the water whose room it occupies. Now, a floating body must be pressed up with a force equal to its own weight, otherwise it would sink lower; hence, when at rest, it must displace its own weight of the water. A solid, as AB in fig. 13, sinks until the space occupied by the part B immersed would contain an amount of water equal in weight to the whole solid AB.

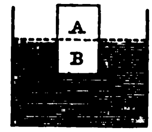

Fig. 13.

By measuring how many cubic feet of water a floating body, such as a ship, displaces, we can thus know its weight, by allowing 1000 ounces for every cubic foot. If we knew previously the weight of the ship and rigging, the difference would give the weight of the cargo. As the buoyancy of a body thus depends on the relation between its weight and the weight of an equal bulk of the liquid, the same body will be more or less buoyant, according to the density of the liquid in which it is immersed. A piece of wood that sinks a foot in water, will sink barely an inch in mercury. Mercury buoys up even iron. Sea-water is denser than fresh water, in the proportion of 1026 to 1000. A ship, then, that carries 1026 tons on the sea, would carry only 1000 tons on a fresh-water lake.

The human body has almost the same weight as an equal bulk of water. When the lungs are full of air, it is slightly lighter, and will float with a bulk of about half the head above water. A person, then, that cannot swim, but has presence of mind to lie flat on the back, with the back part of the head submerged, may, by keeping the lungs full, continue to float with the face above water; but if any other part of the body, as a hand, is raised above the surface, the whole head goes immediately under. Swimmers, by the action of hands and feet against the water, keep the whole head, and often more, above the surface. A body which would sink of itself, is buoyed up by attaching to it a lighter body; the bulk is thus increased without proportionally increasing the weight. This is the principle of life-preservers of all kinds. The most common are those which consist of pieces of cork, or other very light material, attached to the upper part of the body. But air-tight bags are preferable, as they may be said scarcely to encumber the body when empty, and, as danger approaches, they can be inflated with ease by being blown into. Life-boats have large quantities of cork in their structure, and also air-tight vessels made of thin metallic plates; so that, even when the boat is filled with water, a considerable portion of it still floats above the general surface. The bodies of some animals, as sea-fowl, and many other species of birds, are considerably lighter than water. The feathers with which they are covered add very much to their buoyancy. Fishes are enabled to alter their buoyancy by means of an air-bag, which they can inflate at pleasure by an apparatus for generating gases.*

The heaviest substances may be made to float by shaping them so as to make them displace more than their own weight of water. A flat plate of iron sinks; the same plate, made concave like a cup or boat, floats. By making the sides of an iron vessel double, with a considerable air-tight space between the plates, the vessel would be prevented from altogether sinking, even when filled with water.

* The bodies of most fishes are nearly of the specific gravity of water, and therefore, if living in it without making exertion, they neither sink nor swim. When this subject was less understood, many persons believed that fishes had no weight in water; and it is related as a joke at the expense of the philosophers, that a king having once proposed as a task to his men of science to explain this extraordinary fact, many profound disquisitions came forth, but not one of the competitors thought of trying what really was the fact. At last a simple man [who doubted the fact] balanced a vessel of water in scales, and on putting a fish into it, shewed a scale preponderating, just as much as if the fish had been weighed alone.—*Arnott's Elements of Physics.*

The buoyant property of liquids is independent of their depth or expanse, if there be only enough to surround the object. A few pounds of water might be made to bear up a body of a ton-weight; a ship floats as high in a small dock as in the ocean.

The *stability* of a floating body depends upon the relative position of two points—the centre of gravity of the body itself, and the centre of gravity of the water displaced, which is called the *centre of buoyancy*. Since the downward pressure is concentrated in the centre of

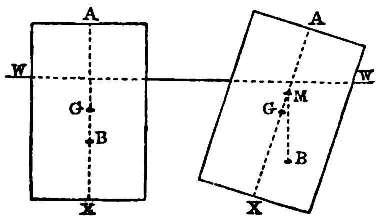

Fig. 14.

gravity G of the floating body (fig. 14), and the upward at B, the centre of gravity of the space from which the water is displaced, there will be equilibrium when the two are in the same vertical line. When the body is moved to one side, B and G are no longer vertical; the line of upward pressure does not pass through the centre of gravity, but meets the axis of the body at a point M, called the *metacentre*, or *beyond the centre*. This point is nearly constant in position for small inclinations on either side. If it lie above the centre of gravity, it is evident that the upward pressure of buoyancy will tend to turn the body about its centre of gravity back towards its original position; if it is below, the body is pushed further and further from that position, and is thus upset. It is thus an object to have the centre of gravity of a vessel as low as possible, in order to secure its stability. With this view, heavy materials, in the shape of ballast, are placed in the bottom, and heavy cargo is stowed low in the hold.

SPECIFIC GRAVITY.

If a lump of sulphur is weighed in air, and found to be two ounces, when weighed in water it will be found to weigh only one ounce. Now, as we know that the weight which a body loses in water is exactly the weight of an equal bulk of water, we infer that a body of water equal in size to the lump of sulphur weighs an ounce. Bulk for bulk, then, sulphur is twice as heavy as water, or their weights are as 2 to 1. In the same way, if a piece of cast iron, of say thirty-five pounds' weight, is weighed in water, it will lose about five pounds; cast iron, then, is about seven times as heavy as water, or their weights are as 7 to 1. By thus referring substances to water as a standard, we get a convenient view of their comparative densities, or *specific gravities*, as the term is. The specific gravity of a body, then, is its weight compared with that of water, which is generally expressed by 1. Thus, gold is found to weigh about $19\frac{1}{3}$ times as much as an equal bulk of water; its specific gravity therefore is $19\frac{1}{3}$. Others take 1000 as the specific gravity of water; and by this scale that of gold is 19,325.

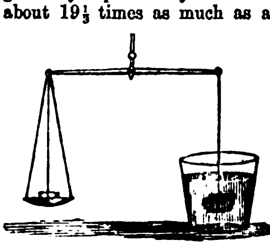

Fig. 15.

The apparatus used in such experiments is called the hydrostatic-balance, a simple form of which is represented in fig. 15. One application of it is to detect whether gold is alloyed. Knowing how much weight a pound of pure gold should lose in water, if an object said to be gold is found to lose more than the right proportion, it is a proof that it is adulterated with some more bulky metal.

In ascertaining the specific gravity of solids that are lighter than water, and of such as melt in it, various expedients must be had recourse to; but the principle in all is the same. To determine the specific gravity of a liquid, take a known weight of any solid that does not melt in the liquid or in water, and that is heavier than either, and observe its loss when weighed in water, and also when weighed in the liquid. These losses are the weights of equal bulks of water and of the liquid, and therefore express their comparative densities; and if the loss in the liquid is divided by that in water, the quotient will be the specific gravity of the liquid, that of water being 1. Thus, a cubic inch of lead loses 253 grains when weighed in water, and only 209 grains when weighed in rectified spirit; therefore a cubic inch of rectified spirit weighs 209 grains, an equal bulk of water weighing 252; and so the specific gravity of water is about a fourth greater than that of the spirit.

Instruments for readily indicating the specific gravities of liquids are called *hydrometers*. The name is derived from two Greek words, signifying *measure of water;* but it is of course used for ascertaining the density of all kinds of liquids. There are various kinds of hydrometers. The illustration here given shews one of great delicacy and exactness. It consists (fig. 16) of a ball of glass *b*, about three inches diameter, with another *c*, joined to it, and opening into it, of one inch diameter, and a brass neck *d*, into which is screwed a wire *ae*, divided into inches and tenths of an inch, about ten inches long, and one-fortieth of an inch in diameter. The whole weight of the instrument is 4000 grains when loaded with small weights, such as shot, in the lower ball *c*. When plunged into water in the jar, this instrument is found to sink an inch if a single grain be laid upon the top *a*; hence a tenth of a grain sinks it a tenth of an inch. So great is the delicacy of this hydrometer, that a difference in specific gravity of one part in 40,000 can be detected. To find the gravity of fluids lighter or heavier than the standard of comparison, the shot in the ball can be altered as required. As heat expands liquids, rendering them specifically lighter, great attention must be paid to the temperature of those experimented upon, as otherwise wrong results will be obtained. Spirits, for instance, will be apparently stronger in hot weather than in cold.

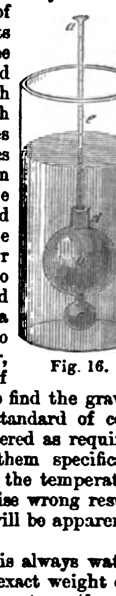

Fig. 16.

For solids and liquids, the standard is always water; it is therefore important to know the exact weight of a certain bulk of water at a fixed temperature (for the bulk alters with the temperature). Now, it is found that at the temperature of 62°, a cubic inch of distilled water weighs 252·458 grains; therefore a cubic foot weighs 997 ounces avoirdupois, or very nearly 1000 ounces. If, then, gold is nineteen times heavier than water, a cubic foot of gold will weigh 19,000 ounces; and so of any other substance.

The heaviest substance known is platinum, whose specific gravity is 22. There are metals, again, lighter than water, as potassium and sodium. One liquid, mercury, has a specific gravity of $13\frac{1}{2}$; ether is only 0·715. The lightest substance known is hydrogen gas. The standard of comparison for gases is atmospheric air, which is about 800 times lighter than water. Its specific gravity is taken at 1000. Hydrogen is fourteen times lighter than air; while carbonic acid and chlorine are more than twice as heavy as air. The vapour of iodine is eight times the weight of atmospheric air.

HYDRAULICS.

We are now to consider the phenomena of water in motion, and acting as a moving power.

FLOW OF WATER THROUGH APERTURES AND PIPES.

If three apertures, A, B, C, are made at different heights in the side of a vessel (fig. 17) filled with water, the liquid will pour out with greater impetuosity from B than from A, and from C than from B. The velocity does not increase in the simple ratio of the depth. The exact law of dependence is known as the theorem of Torricelli, and is to this effect:—'Particles of fluid, on issuing from an aperture, possess the same degree of velocity as if they had fallen freely, *in vacuo*, from a height equal to the distance of the surface of the fluid above the centre of the aperture.' The jet from B, for instance, has the same velocity as if the particles composing it had fallen in vacuo from H to B. Now, the velocity acquired by a body in falling is as the time of the fall; but the space fallen through being as the *square* of the time (see NATURAL PHILOSOPHY), it follows that the velocity acquired is as the square root of the space fallen through. In the first second, a body falls 16 feet, and acquires a velocity of 32 feet. If C, then, is 16 feet below H, a jet from C flows at the rate of 32 feet; and if A is at a depth of 4 feet, or one-fourth that of C, the velocity of the jet at A will be half the velocity of that at C, or 16 feet. In general, to find the velocity for any given height, multiply the square root of the height by $\frac{16}{2}$, or 8. The height of the water in the reservoir above the issue is technically called the 'head.'

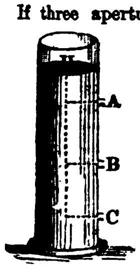

Fig. 17.

When, by means of the area of the opening and the velocity thus determined, we calculate the number of cubic feet or of gallons that *ought* to flow out in a given time, and then measure the quantity that actually does flow, we find that the actual flow falls short of the theoretical by at least a third. In fact, it is only the central part of the jet, which approaches the opening directly, that has the velocity above stated. The outer particles approach from all sides, with less velocity; they jostle and crowd one another, as it were, and thus the flow is retarded. In consequence of this want of uniformity in velocity and direction among the component layers of the jet, as they enter the orifice, there takes place what is called a 'contraction of the vein' (*vena contracta*); that is, the jet, after leaving the orifice, tapers, and becomes narrower. The greatest contraction is at a distance from the orifice equal to half its diameter; and there the section of the stream is about two-thirds the area of the opening.

It has as yet been supposed that the issue was by means of a simple opening or hole in the side of the vessel; but if the flow takes place through a short tube, the rate of discharge is remarkably affected. Through a simple opening, the actual discharge is only about 64 per cent. of the theoretical; through a cylindrical conducting-tube, or *adjutage*, as it is called, of like diameter, and whose length is four times its diameter, the discharge is 84 per cent. The effect is still greater if the discharge-tube is made conical both ways, first contracting like the contracted vein, and then widening. The effect of a conducting-tube in increasing the discharge is accounted for by the adhesion of the water to its sides, which widens out the column to a greater area than it would naturally have. It has thus a tendency to form a vacuum in the tube, which acts like suction on the water in the reservoir, and increases the quantity discharged.

The flow is more free if the orifice is in the bottom of the vessel, than in the side on a level with the bottom. If the discharge-tube is made to project inwards beyond the thickness of the walls of the vessel, the velocity is much impeded, owing to the opposing currents produced by the water approaching the opening.

Pipes.—The pressure and velocity with which water enters a conduit-pipe become more and more reduced by friction as it proceeds. The rate of reduction depends upon the diameter of the tube, its length, the bendings it undergoes, &c. The resistance to the flow of water in pipes does not arise properly from friction, as understood of solids, but from the adhesion of the water to the sides of the pipe, and from the cohesion of the watery particles among themselves; it makes little difference, therefore, whether an earthenware pipe, for instance, be glazed or not. Large projections form an obstacle; but mere roughness of surface is filled up by an adhering film of water, which is as good as a glaze. The resistance increases greatly with the narrowness of the pipes. Engineers have formulæ, deduced in great part from experiment, for calculating the discharge through pipes of given length and diameter, and with a given head; but the subject is too complicated for introduction here.

The flow of water through a pipe, when regulated by valves, is more or less impeded according to the form of valve used. A valve like the throttle-valve of a steam-engine (see STEAM-ENGINE), causes a double contraction, the water dividing to form two currents, one on each side of the valve; a conical valve, like that of a safety-valve, causes a like contraction. The best form of valve is the ball-valve with an aperture through it; by turning it round in its seat, the aperture is closed or opened.

Rivers.—The effects of friction between liquids and solids are nowhere so conspicuous as in the flowing of rivers. The natural tendency in the water to descend at a certain speed, is checked by friction, by bends in the course of the stream, and by projections on the banks and bottom. From these causes, the water in a river flows with different velocities at different parts in any vertical section across the current. It flows at a slower rate of speed at and near the bottom than at the surface, and also slower at the sides than at the middle. To get the mean velocity of a river or other stream, find first the surface velocity at the central part of the stream, by observing the rate in feet per minute at which a floating body is carried down. The float should be such as barely to reach the surface, so as not to be affected by the wind. If, from the square root of this surface velocity, we substract one, and then square the remainder, we get the bottom velocity. Half the sum of the surface and bottom velocities then gives the mean velocity;

and if this is multiplied by the area in feet of the cross-section of the stream, the product is the discharge in cubic feet per minute.

The abrasion of the banks and bottom of a canal or river depends upon the velocity. A velocity of 30 feet per minute will not disturb clay with sand and stones; one of 40 feet will sweep along coarse sand; of 60, fine gravel; of 120, rounded pebbles; and of 180, angular stones. The action on the banks is much lessened by making them sloping or shelving. Oblique currents in rivers or canals are caused by the presence of obstructions in the water-way, as rocks or stones. The water striking against these is deflected, and thrown against the bank opposite; hence those parts of the sides are much abraded. It is this unequal wearing away of the banks of rivers that gives them their serpentine character; which is most observable in flat countries, as, where the velocity of the current is considerable, it overcomes comparatively small impediments, and dashes forward in a straight course.

Resistance of Water to Bodies moving through it.—This is greatly affected by the shape of the body, which ought to have all its surfaces oblique to the direction of the motion. Hence ships, to sail well, must present sharp angles both at bows and stern. The best form in all respects for ships is still a disputed point, though it seems to be agreed that swift-swimming fish present the nearest approach to the true model.

The resistance offered to a moving body in water is as the square of the velocity; thus, with a double rate of speed, the resistance is four times. This is easily explained:—A vessel moving at the rate of one mile per hour displaces a certain quantity of water, and with a certain velocity; if it move twice as fast, it of course displaces twice as many particles in the same time, and requires to be moved by twice the force on that account; but it also displaces every particle with a double velocity, and requires another doubling of the power on this account; the power thus twice doubled becomes a power of four. When the body is moved with a speed of three or four, a force of nine or sixteen is wanted; and so on. Thus the resistance increases as the square of the speed.

This law is of great importance in practice. For instance, in steam-navigation, if an engine of fifty horse-power impel a vessel at the rate of seven miles an hour, it would require two of the same power to drive her ten miles an hour, and three such to drive her twelve miles an hour; hence the enormous expense of fuel attending the gaining of a high velocity.

The resistance offered to a floating vessel is greater in a canal than in a wide river or the sea. The water before the bow rises higher than the mean level, forming an incline from this to the stern; the narrower the canal, the greater the angle of this incline.

Waves.—Waves are the risings and fallings of the water, caused by some power, such as the blowing of the wind. The power, whatever it happen to be, communicates a force to the mass of liquid, and a series of undulations is the consequence.

These undulations or waves exhibit the transmission of the communicated force. The force does not advance or alter the lateral position of the water at any given point; it only alters the water in its vertical position, or in relation to its depth. When, therefore, waves advance, the water does not advance with them: the water but rises and falls, and assumes the figure of undulations on its surface. When the undulations approach a shallow shore, the water then acquires a progressive motion; and by friction on the bottom, or impulsion against the shore, the communicated force is exhausted. The shaking of a carpet affords an exact representation of the action of waves or undulations.

Waves are comparatively superficial; they seldom rise to a height of more than twelve feet above the level of calm water, and make an equal descent beneath, making altogether a difference of level of twenty-four feet: at eight or ten feet below the intervening hollow or trough of the waves, the water is tranquil. Waves 'mountains high' is only a figure of speech.

For motion in liquids produced by difference of temperature, see HEATING AND VENTILATION.

HYDRAULIC MACHINES.

Inverted Syphon.—The tendency in a liquid to find its level, furnishes, by means of a bent tube, one of the simplest and most useful of all hydraulic machines.

Fig. 18.

Its application is illustrated in fig. 18. A pipe is represented proceeding from a lake on the top of a hill down into a valley, and thence supplying a house situated on the opposite rising-ground. This contrivance supersedes the necessity of an aqueduct. From the pipe, in its passage across the valley, a small tube is carried to supply an ornamental fountain or jet d'eau. The water spouts from this jet d'eau with a force corresponding to the height of the lake above.

Water-meter.—The extended use of the 'constant system' of water-supply to houses, &c., has necessitated some means by which the quantity given can be registered, just as gas is measured when supplied to houses. Not only for this, but for a variety of purposes in the arts, is a good water-meter desiderated. It is impossible, under our present head, to give even a slight sketch of the numerous machines of this kind which have been introduced during the last few years. A very successful kind, which has been introduced to a large extent in Manchester and elsewhere, is that known as Taylor's patent.

A novel, and, as it appears, an efficient water-meter, has recently been introduced at the Salford Waterworks: in its arrangement, it differs from all others hitherto introduced.

The hydraulic-ram is a simple and conveniently applied mechanism, by which the momentum or weight of falling water can be made available for raising a portion of itself to a considerable height. In the figure annexed, the pipe *a* is that which leads the water from the source or spring, which might otherwise be allowed to run to waste, to the pipe *b*; at the end of this a valve, *e*, is situated, opening downwards and so weighted that it is capable of falling by its own weight, against the pressure of the column or head of water, when not in motion. Suppose the valve has fallen, and allowed a flow to take place along the tube; the water soon acquires momentum sufficient to force up the valve. This stops the flow, destroys the momentum, and leaves the valve again to fall. There thus takes place a succession of openings and shuttings of the valve; and at each shutting, the arrest of the momentum of the current causes a shock throughout the tube, which forces up another valve at *f*, opening

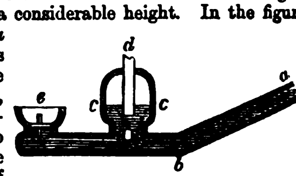

Fig. 19.

into an air-vessel *cc*, and injects a quantity of water into it. A tube, *d*, enters this air-vessel, and a stream of water is propelled up it, on the principle of the fire-engine (see fig. 31). The higher the source is above the valve *e*, the higher will the water be raised. The proportion of water lost by flowing through the valve *e*, to that sent up the pipe *d*, is very considerable; but from the continuous action of the mechanism, a large supply is soon obtained. In well-constructed rams, the mechanical effect obtained should be from 65 to 75 per cent. of the force supplied. For raising comparatively small quantities of water, such as for single houses, farm-yards, &c., the ram is the most superior mechanism yet introduced. The concussion, and consequent deterioration of the valves, places a limit to the use of this mechanism when applied to raise large quantities.

Bramah's Press.—The principle of the hydrostatic paradox (see p. 226) is turned to account in what is termed the hydraulic-press, invented by Bramah, in which a force-pump is used. In fig. 20, we give an

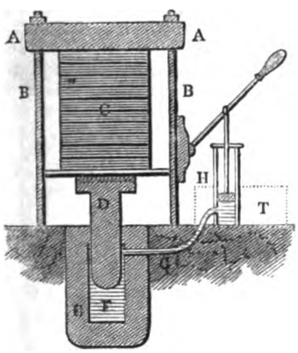

Fig. 20.

illustration of the arrangement used. B, B are pillars supporting the entablature AA, E the cylinder into which the piston D works; the water is passed into the cavity of the cylinder F, and forces up the piston and its table, thus pressing the bales, books, &c., C, with great force against the entablature AA. The water is forced from the tank or cistern T, by the force-pump H, through the pipe G, into the interior of the cylinder. The whole arrangements here shewn are of the simplest nature, the complicated mechanism adopted in practice not requiring to be introduced for our purposes.

The power of the hydraulic-press is readily calculated. Suppose that the pump has only one-thousandth of the area of F, and that, by means of its lever handle, the piston of the pump is pressed down with a force of 500 pounds, the piston of the barrel will rise with a force of one thousand times 500 pounds, or more than 200 tons. The rise, however, will be slow in proportion to the gain of power.

Water-power—Impact Wheels.—In using the impulse of water to act upon the various forms of water-wheels, the theoretical effect obtained is that which is expressed by multiplying the head of water, or the height from which it falls, by the weight of the water discharged in one minute. In practice, many modifying circumstances tend to reduce this effect materially; a considerable portion of the power being lost by friction, the distance of the wheel from the 'gate,' and numerous other causes.

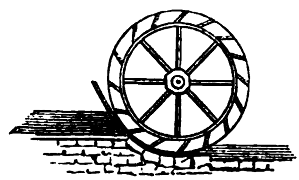

Fig. 21.

The simplest form of water-wheel is that known as the undershot, illustrated in fig. 21; it is only used in cases where the fall of water is low, or a high velocity is to be imparted to a small wheel. The gate should deliver the water as close to the wheel as possible; and the contraction of the flowing vein should be directed to the centre of the paddle. The channel in which the wheel works, should be only wide enough to admit of its free working. When performing the greatest amount of labour, the velocity of an undershot wheel is half that of the water in the channel—the point measuring the velocity of the wheel being taken at the centres of the paddles. The labour performed decreases as this velocity is increased; wheels of twenty feet diameter, if well constructed, may give as much as 33 per cent. of the power of the stream; smaller wheels will not give more than 25 per cent. In any case, however perfectly arranged, this form can never give more than one-half of the power. Where undershot wheels act in wide streams, the paddles are inclined to the diameter; the water rises upon them, and acts by its weight as well as impulse: if this inclination is 30°, the greatest effect is obtained.

Wheels with curved buckets are much more effective than those with radial paddles. Curved buckets should be used where the fall of water exceeds twelve feet, the water being introduced to the wheel a little below the highest point. Wheels thus used are termed overshot; a form is illustrated in fig. 22. When this laying of the water at the highest point is not practicable, it is

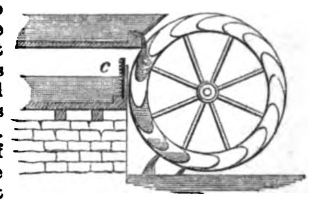

Fig. 22.

introduced at a lower point, as at *c*; the wheel thus arranged is sometimes termed a breast-wheel, when open buckets or paddles are used. Breast-wheels thus constructed are not economical, and are rarely used. In wheels such as the last figure illustrates, the water should be introduced so as to fall directly on the bottom of the buckets, not touching the backs. The speed of the circumference of the wheel should be a little less than half the height of free descent of bodies in the first second—that is, eight feet. The loss of power is increased by the buckets freeing themselves of water too soon, as well as too late; in the latter case, the wheel has to lift a certain weight of water needlessly. Where water is scarce, a slow-moving wheel and a strongly curved bucket will be found most advantageous. Curved buckets are not adapted for undershot wheels. In overshot wheels, the higher they receive the water, the slower the wheel moves, and the more curved the buckets may be, care being taken to allow the air to escape. This has been effected in the form of ventilating bucket introduced by Fairbairn. The amount of labour performed by overshot wheels varies from 10 to 65 per cent. of the power of water imparted.

Reaction from the Efflux of Fluids.—When a vessel filled with water has no outlet, the outward pressure on the sides has no tendency to push the vessel out of its place, because the pressure on any spot is counteracted by an exactly equal pressure on some other spot. But when an opening is made, as at A, B, or C (fig. 17), the pressure is less on that side of the vessel than on the other, and if the vessel were standing on a piece of wood floating on water, it would be seen to move in a direction opposite to the jet. A jet of air or steam has a similar effect to one of water. A tea-kettle mounted on wheels, with a spirit-lamp below it to make it boil, retreats from the current of steam that issues from the spout. This phenomenon is similar to the recoil of a musket, and may be considered as an instance of the law of reaction.

It is on this principle that water is made to act as

a moving power in what are called reaction wheels. Of this nature are the machines known as Barker's Mills. In the accompanying diagram (fig. 23), the apparatus consists of a vertical tube AB, moving freely on a pivot C, and receiving a supply of water from a stream D. This water is discharged by two opposite horizontal arms *e*, *e'*, the jets issuing in contrary directions, and by their reaction causing a rapid rotatory motion of the whole machine. The most approved form of reaction or centrifugal wheel is Fourneyron's Turbine, for a description of which we must refer to practical treatises on hydraulics. One drawback in horizontal wheels, or turbines generally, is the weight with which the mass of water presses on the pivot of the upright axle, thus causing great friction. This is obviated in some turbines by making the water enter the wheel from below, as represented in fig. 24;

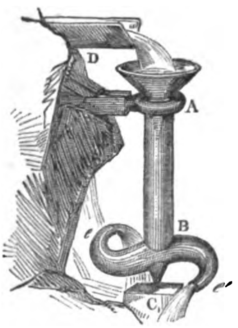

Fig. 23.

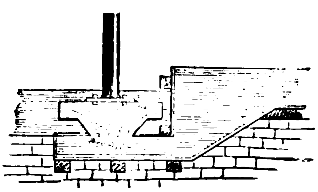

Fig. 24.

the greater part of the weight of the machine is thus supported by the water.

PNEUMATICS.

Pneumatics, from the Greek word *pneuma*, 'breath,' or 'air,' is that branch of science which treats of the weight, pressure, motion, and other mechanical effects of aëriform bodies. Modern science has made us acquainted with a number of distinct *airs*, besides common air; these are now usually called *gases*, and the name *air* is confined to the fluid composing our atmosphere. This itself is not a simple substance; it is a mixture of two distinct gases, oxygen and nitrogen. It belongs to Chemistry to explain the different natures of these two; it is only with the mechanical effects that we have at present to do, and in this respect the mixture acts as if it were a simple gas.

Aëriform fluids differ from one another in weight as well as liquids do (see p. 230). But, except as to specific gravity, the properties of air treated of in pneumatics are true of aëriform fluids generally. It is only the equilibrium of air that will be considered in this place; the phenomena of air in motion fall more conveniently under METEOROLOGY, VENTILATION, &c.

An *atmosphere* of air surrounds the globe like a continuous ocean, many miles in height. Air in small quantity appears *colourless*, owing to its extreme rarity; but when we look through a considerable depth of it, it is seen to be really blue. Hence the peculiar tint of the sky, and the blue colour of distant mountains. The blue is purer and brighter the less vapour is mixed with it. Were it not for the atmosphere, the heavens would appear as a perfectly black vault; and on very high mountains, where the greater part of the air is below, they are said to approach to black.

WEIGHT OF AIR.

The idea of air as a material fluid possessing weight and exerting pressure on everything immersed in it, is modern. The ancients thought of it as essentially *light*, or without weight, and as wanting generally the characteristics of matter; and they used the same words for 'breath,' 'air,' as for 'spirit,' 'life.' Yet it really possesses all the properties of matter, as surely as water does. A portion of it may be much compressed, indeed, but cannot be squeezed to nothing; it still occupies space, and is therefore *impenetrable* (see NATURAL PHILOSOPHY). It also resists sensibly a flat body, such as a fan moving through it; and when itself in motion, as in a strong wind, it is felt to have a powerful momentum or moving force.

With regard to the *weight* of air, nothing in the history of science is more remarkable than that men should have lived so long subject to the great pressure which this weight occasions, without discovering it. The fact is, that air acts so little on the senses, that it does not make us aware directly of its existence. The effects produced by its weight were therefore attributed to other causes. The facts, for instance, that go by the name of *suction*, are all owing to the pressure of the atmosphere. But when water was seen to rush up a pipe from which the air was withdrawn, it was explained by saying that 'nature abhors a vacuum,' that is, an empty space. This explanation continued to satisfy philosophers till the middle of the seventeenth century. Some mechanicians near Florence, having to construct a pump of unusual length, found, to their surprise, that the water refused to rise higher than thirty-two feet. This led to the conjecture that the weight of the atmosphere was the cause of water rising in the pump, and Torricelli, the pupil of Galileo, confirmed the conjecture by a happy experiment.

Mercury weighs $13\frac{1}{2}$ times as much as water. If, now, he argued, the atmospheric air can support a column of thirty-two feet of water, it must also be able to sustain a column of mercury of about one-fourteenth that height. The experiment is easily made. A glass tube of upwards of thirty inches in length, and closed at one end, is filled with mercury; and the finger being firmly pressed on the open upper end, the tube is inverted, and the end closed by the finger is plunged into a vessel containing mercury, CD. The finger being now withdrawn, the liquid in the tube descends, however long the tube may be, till it stands at the height of about thirty inches above the level of that in the vessel.

Fig. 25.

All doubt on the subject was shortly after put an end to by the celebrated Pascal, who caused the Torricellian tube, as it was called, to be carried up the Puy-de-Dôme, a mountain in France. By ascending a mountain, a part of the atmosphere is left below; if it is the pressure of the superincumbent atmosphere, then, that sustains the column, the mercury must sink further and further as the elevation is greater. Such was found to be the case, and the question was set at rest for ever.

That air is ponderable, or has weight, can be put to direct proof. By means of an instrument called an air-pump, to be afterwards described, vessels of a certain construction can be emptied of the air that in ordinary circumstances fills every space not occupied by other matter. When a hollow globe of glass or of copper, holding a cubic foot, is thus emptied of air, and weighed, on admitting the air again, it is found to be about an ounce and a quarter heavier than before. As a cubic foot of water weighs 1000 ounces, water is thus about 800 times heavier than air.

The tube of Torricelli gives us an exact measure of the weight and pressure of the whole atmosphere. If the tube (fig. 25) is an inch in area, the column of mercury, PE, thirty inches high, weighs about fifteen pounds. This weight rests on the mercury within the tube at P, the level of the general surface, and, by the law of liquid pressure already established, would press it down, and raise the level of the surface without, were not that surface equally pressed by the atmosphere. The atmosphere, then, rests with a weight of fifteen pounds on every square inch of surface. By multiplying the number of inches on the surface of the globe by fifteen, the product is the weight of the whole atmosphere in pounds. It is the same as the weight of an ocean of mercury spread over the whole globe to the uniform height of thirty inches, or of one of water thirty-four feet deep, or of one of oil thirty-seven feet deep.

THE BAROMETER.

In the Torricellian tube above described, we have the well-known instrument called a *barometer* (from two Greeks words signifying 'weight,' and 'measure'). The weight of the atmosphere is liable to fluctuations, and these are marked by the rising and sinking of the top of the column at E, which varies, at the level of the sea, from 28 to 31 inches, the average height being 29·7. A scale is attached to the tube to mark the rise and fall. It is important to observe that the height of the column is counted from the level of the mercury in the open vessel, and that this level is not steady. If the column sink, for instance, part of the mercury in the tube descends into the basin, and raises the level of the surface. When the basin is comparatively wide, the rise is insignificant, and is seldom attended to; but where great accuracy is required, either the scale is so constructed as to allow for the alteration of level, or the bottom of the basin is made flexible, and can be raised up and down by a screw, so as to bring the surface of the mercury always to the same point on the outside of the tube.

Barometers are of various constructions, according to the uses they are intended for. The common *weather-glass* consists of a glass tube, upwards of thirty inches in length, closed at one end A, and bent upwards at the open end C, as represented in fig. 26. The mercury requires to be introduced with great care into the tube, and boiled in it to expel all air; so that when it sinks down there may be a perfect vacuum at AE. The height of the column sustained is here to be counted from E down to a point on the tube on a level with F, the surface of the fluid in the open end. On the surface of F there floats a small ball, from which a thread is passed over a pulley G, and kept stretched by a lighter ball W. When the column at E sinks, the surface at F rises, and carries up the float, and the friction of the string turns the pulley, and with it the index H, whose motions are marked by a graduated circle. Such instruments are not capable of any great accuracy in ascertaining the actual height of the column; they indicate, however, generally whether it is high or low, and whether it is rising or falling, and these are the chief points in prognosticating the weather. (See METEOROLOGY).

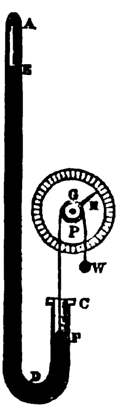

Fig. 26.

ELASTICITY OF GASES.

The laws which regulate the pressure of gases are essentially the same as those already established with regard to liquids. The fundamental fact of *transmitting pressure equally in all directions*, is as true of the one class of substances as of the other. But the effects in the case of gases are much modified by their peculiar property of *elasticity*, which requires careful consideration. The elasticity of gases involves two things—compressibility and expansibility, and in the case of common air, both properties are without any known limit.

1. Air is unlimitedly *compressible*, and that according to a remarkable law. Let *ab* be a barrel or cylinder twelve inches long, closed at *b*, and open at *a*, having an air-tight piston, *d*, moved up and down by the rod *c*. Before the piston is inserted, the air in the cylinder sustains the usual pressure of the atmosphere, which is resting upon it at the open end *a*; and if the area is an inch, the amount of the pressure is 15 pounds. When the piston is placed on the open end, and about to enter, the direct action of the outer air is cut off, but it continues to act on the upper side of the piston, so that the column inside still sustains 15 pounds. Let the rod be then loaded with weights till the piston descend through half the cylinder, so as to squeeze the confined air into half its original bulk; it will be found that 15 pounds have been laid on. The piston is now forced down with a weight of 15 pounds in addition to the weight of the outer atmosphere; the pressure on the confined air is thus exactly *doubled*, and the effect is to compress it into *half* the space. If the weight is *tripled* by adding 15 pounds more, the piston descends two inches further to *e*, and the air is reduced to *one-third* of its original bulk. An additional 15 pounds, making in all *four* atmospheres, will sink it to *f*, *one-fourth* from the bottom; and *twelve* atmospheres will leave the air confined between *b* and *g*, *one-twelfth* of the whole space. This regular progression, which is known as *Mariotte's Law*, from the name of its discoverer, holds good, without variation, for atmospheric air up to at least twenty-seven atmospheres.

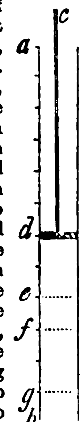

Fig. 27.

It follows from this that the elastic force or tension of compressed air—that is, the force with which it seeks to expand—is exactly equal to the compressing force, and inversely, as the space it occupies. At *f*, the air in the cylinder reacts upon the piston with a force of four atmospheres; at *d*, where it occupies twice the space, it presses up the piston with a force of only two atmospheres; at *a*, the under side of the piston is pressed with a force of one atmosphere, so as exactly to balance the weight of the external air.

2. Air is *expansible* without limit. The spring of air is not like that of a compressed feather or of a piece of India-rubber, which loses its tension as soon as it regains its original condition; air cannot be said to have any original volume, for it is always striving to occupy a larger space. Suppose an opening at the bottom of the cylinder (fig 27), and let the piston be at *f*; its upper and under sides sustain each 15 pounds, for the external atmosphere is admitted to both; and air, like water, presses equally in all directions, up as well as down. If the opening is now closed by a plug or a stop-cock, cutting off the external air from acting on the under side, the piston will not move, because the confined air presses on the under side, not by its weight, but by its expansive force, as much as the external air on the upper. Let the piston be next drawn upwards, and the air will not only follow it, but will continue to press upon the under side of it, though with a diminishing force. When the piston has risen to *d*, the air occupies twice its original bulk, and its tension or pressure against the under side of the piston is reduced to one-half, or $7\frac{1}{2}$ pounds; and if its volume is again doubled by drawing the piston to *a*, its elastic force falls to one-fourth, or $3\frac{3}{4}$ pounds. Thus the law of Mariotte holds for rarefied air as well as for condensed air. If the piston is drawn up with the hand, the gradually diminishing elastic force of the air within the

cylinder is sensibly felt. What the hand has to sustain, beyond the resistance of friction, is the difference between the two pressures on the opposite sides of the piston. That on the upper side continues a constant weight of 15 pounds; at starting from *f*, the two are equal, but the difference gradually increases until at *a* it is 11¼ pounds.

HEIGHT OF THE ATMOSPHERE.

If we assume air at the level of the sea to be, in round numbers, 800 times lighter than water, then, since water is 13½ times lighter than mercury, it follows that air is 13½ × 800, or nearly 11,000 times lighter than mercury. In order, therefore, to balance the column of mercury in the barometer, which is 2½ feet high, a column of air of the above density would require to be 11,000 times 2½ feet, or 27,500 feet high, which is nearly five miles. And this would actually be the height of our atmosphere if air were, like water, of uniform density throughout its whole depth.

It is evident, however, that the atmosphere is many times higher than five miles. Light clouds are seen floating above the highest mountains, such as Kinchinjunga, which exceeds 28,000 feet. And not only this, but we know, from the elastic property of air above explained, that the atmosphere cannot be uniform to the top, but must become rarer and rarer as we ascend. An ascent of about 500 feet from the level of the sea, makes the barometer fall half an inch, shewing that a sixtieth part of the weight of the atmosphere is left below. The air at this height, then, is relieved of $\frac{1}{60}$th of the pressure that confines it at the sea-level, and by the law of elasticity, becomes proportionally enlarged in volume; so that to get above another sixtieth part of the mass of the atmosphere, we must ascend more than 500 feet; and so on in increasing ratio. At the height of about three miles, one-half the mass of the air is below; the density at that point is reduced to one-half, and an ascent of 500 feet would produce only half the fall of the barometer that is produced at the earth's surface. The upper half of the atmosphere must thus occupy a depth many times that of the lower half. The regular progression in the increasing rarity of the successive strata of the atmosphere, which would arise from Mariotte's law, is true only on the supposition that the temperature is the same throughout. But the capacity of air for heat increases with its rarity, so that the temperature of the atmosphere diminishes as we ascend. This loss of heat diminishes the elastic force of the air in the upper regions, and makes it expand less under the diminished pressure than it would otherwise do. Cold, then, may be said to check the indefinite upward extension of the atmosphere. As this cold goes on increasing, and also the distance between the atoms of the air, the repulsive force which tends to separate the atoms further and further, must at last become so weak, that the gravity of the upper layer of atoms is able to resist it, and to keep them from rising higher. It would thus appear from theory, that there is a definite boundary to the atmosphere; and from observations made as to the effects on rays of light in passing through the upper regions of the air, it is concluded that the limit of its height is forty or fifty miles.

Measurement of Heights by the Barometer.—Though the same difference of elevation does not at all stages in the ascent give the same rise or fall of the barometer, yet, by means of the known law of expansion, it is possible, from knowing the heights of the barometer at two stations, and a number of other circumstances, to calculate the elevation of the one above the other. Besides the height of the barometer at the two stations, it is necessary to observe the temperature, for this affects not only the length of the column of mercury in the barometer, but also the density of the atmosphere, both of which must be allowed for. The latitude of the place has also to be taken into account; for the force of gravity varies from the equator to the poles (see NATURAL PHILOSOPHY), and this affects the density of the air. Altogether, the rule is too complex for explanation here.

THE AIR-PUMP.

The air-pump, by which air is removed from vessels, acts by means of the expansibility of the fluid. One form of an air-pump is represented in fig. 28. R is the glass-receiver, or vessel to be exhausted, standing on a smooth plate SS, and fitting so exactly, that no air can penetrate between them. From the middle of the plate, there runs a channel or tube, AB, into the barrel of the pump. The piston, P, is represented as above the opening of the channel, with its rod, C, passing through an air-tight collar D. When the piston is forced down past the opening, it cuts off the air in the barrel from that in the receiver, and compresses it so as to make it open the valve, V, and escape. When P has reached the bottom, and begins to ascend again, the valve closes, and prevents air from entering. In the meantime, the air in the receiver has by its expansion refilled the barrel, and is now rarer; the piston again descends, and expels another portion, and so on. It is obvious that in this way the whole air can never be expelled; as the contents of both receiver and barrel are equally rarefied, each stroke expels less and less. The best air-pump always leaves a residuum.

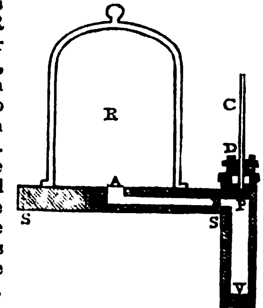

Fig. 28.

The *condensing pump*, or syringe, represented at *ik*, fig. 29, is the counterpart of the exhausting air-pump. By means of it, a receiver can be charged with an amount of air that would fill it many times at the ordinary density, and experiments can thus be tried on bodies enclosed in the receiver, under the pressure of many atmospheres.

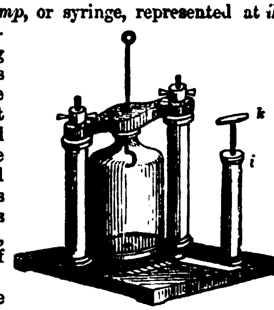

Fig. 29.

A condensing syringe is used for charging the chamber of air-guns. The valve of this chamber being then suddenly opened by the trigger, a portion of the highly compressed air is allowed to escape into the barrel behind the ball, which it propels with great velocity.

By means of the exhausting air-pump, many interesting experiments are performed, illustrative of the pressure of the atmosphere. If a bladder, half full of air, and tightly tied at the neck, be placed under the receiver, as the exhaustion proceeds, the bladder will expand by the removal of the external pressure, and seem as if ready to burst. Dried raisins, or shrivelled apples, will in like manner swell out, and have all the plumpness of new fruit; and an egg, by the expansion of its confined air, will explode. A mouse placed below the receiver, and deprived of air, immediately dies from want of breath.

It is the atmosphere that retards the falling of bodies of a light and porous nature; and therefore, in the exhausted receiver of an air-pump, all such bodies descend with the same velocity as those of a heavy compact nature. A piece of coin and a feather let fall at the same instant of time from a hook within the top of an exhausted receiver, will strike the bottom at the same moment.

Boiling-point under different Pressures.—If water is boiled in a glass flask, and then allowed to cool

several degrees below the boiling-point; on being placed under the exhausted receiver, it will again begin to boil briskly, and will continue to do so for some time. This shews the connection between the pressure of the air and vaporisation. Under the usual pressure, water boils at 212°, alcohol at 172°, ether at 98°, oil at 600°. But as the pressure is removed, the boiling-point in each case becomes lower. On the top of Mont Blanc, water is found to boil at 187°; and in a complete vacuum, liquids in general are stated to boil at a temperature 140° lower than in the open air. Increased pressure, again, raises the temperature of the boiling-point. This is taken advantage of in extracting gelatinous and oily matter from bones, &c. The bones are boiled in a strong vessel where the steam may be confined, and made to press on the liquid. A pressure of two atmospheres raises the temperature to 250°. In distilling liquors, and in making vegetable extracts, on the other hand, it is often desirable to avoid such a high heat as 212°, which is apt to injure the substances, and in such cases the processes are carried on under a partial vacuum. In boiling down the juice of the sugar-cane to the crystallising point, this expedient is employed with great advantage.

It thus appears that boiling water is not equally hot at all places on the earth. At Quito, for instance, which is at an elevation of 9000 feet, water boils at 194°; and this temperature is too low for cooking many substances. Even at the same place, boiling water is hotter on a day when the barometer stands above thirty inches, than when it stands at twenty-eight inches.

Heights measured by Boiling-point of Water.—Vapour of water or steam has a certain tension, or elastic force, according to its temperature (see STEAM-ENGINE). Thus, at 32°, its force is able to sustain 0·2 inch of mercury; at 80°, it supports 1 inch; at 150°, 7·42 inches; at 180°, 15·5 inches; at 212°, 30 inches, or the whole pressure of the air. Now, whatever is the temperature of vapour that can support a given pressure, the same is the temperature at which water boils under that pressure. By observing, therefore, the temperature at which water boils, we can find, from a table of the elastic force of vapour at different temperatures, the pressure in inches of mercury, to which it is subject at the time, and thus make the thermometer a substitute for the barometer. Accordingly, heights are often determined by the boiling temperature of water. Beginning at the level of the sea, a fall of 1° in the boiling-point corresponds to a difference of elevation of 510 feet, or 51 feet for one-tenth of a degree. At an elevation of 2500 feet, the difference for a degree is 520 feet; at 5000 of elevation it is 530; and at 17,000, it is 590. An approximation may be made for medium elevations, by multiplying 530 feet by the number of degrees of difference in the boiling-point between the two stations. Thus, if the boiling-point at the foot of a mountain were 210°, and at the top 202°, the height above the station at the bottom would be about 530 × 8, or 4240 feet. In order to allow for the temperature of the air, &c., certain tables are necessary, such as those given by Colonel Sykes in 'Hints to Travellers' (*Royal Geographical Society's Journal*, vol. 24). 'The results,' says Colonel Sykes, 'of six years' experience justify me in saying that common thermometers may be satisfactorily used to supply the place of barometers in measuring heights where great accuracy is not required; and it will be recollected that what is usually looked upon as a difficult and troublesome operation with barometers, will be attainable by any person who carries with him a couple of thermometers, the requisite tin pot, and the tables, and who is master of the simplest rules of arithmetic.'

The experiment of boiling water under diminished pressure may easily be performed without an air-pump. Take a common olive-oil flask, and fit it with a good sound cork. Fill it one-third with water; and when it has been brought to boil briskly over a spirit-lamp, or a gas flame, insert the cork, withdrawing it from the flame at the same instant, and then place it in a support, bottom upwards. The ebullition will cease after a short time; but by pouring cold water over the upper part of the flask, it can be renewed again and again. The explanation is, that the space above the water in the flask is filled with nothing but steam, and when this is suddenly condensed by cooling the glass, the surface of the water is relieved from pressure, and the boiling is renewed, until the steam generated again cause as much pressure as to check it.

Gases dissolved in Liquids.—Liquids contain a certain amount of air and other gases dissolved in them. The molecules of the dissolved gas adhere apparently to those of the liquid with a certain force, sufficient to condense the gas into much less than its natural bulk; and a liquid can hold more of a gas thus imprisoned the greater the pressure it is under. This is most strikingly seen in the case of effervescing liquids, such as beer. Carbonic acid gas is generated in the beer by fermentation; under the usual pressure of the atmosphere, the liquid can hold a certain amount of this dissolved, and the rest escapes. But when a bottle of it is closely corked, the pressure on the surface continues to increase till it is equal perhaps to two atmospheres, and enables the liquid to hold an additional amount of gas in solution. If the cork is now removed, this additional portion separates from the liquid to which it was adhering in a dense, perhaps liquid form, and starts into its own aëriform shape, appearing as minute globules all through the mass, and rising towards the surface. After standing in an open glass for some time, the beer becomes apparently flat and dead, as if all the gas had escaped. But that this is not the case, may be shewn by placing it under the receiver of the air-pump; on the first stroke, specks of gas make their appearance in all parts of it, and it soon froths up, as if newly drawn.

When a glass of common spring or river water is in like manner placed under the receiver, it is seen to contain a considerable amount of common air dissolved in it. As the exhaustion proceeds, minute globules of air make their appearance all through the water, and rise in a stream to the top. A dense crop of bubbles is observed to form on the sides of the glass; this arises from a film of air having been condensed on the glass by adhesion (see NATURAL PHILOSOPHY) before the water was poured in, and from part of it now escaping under the diminished pressure.

PUMPS.

The effect of atmospheric pressure on water affords a convenient method of raising it above its ordinary level; this is effected by pumps, which may be termed both hydraulic and pneumatic machines. Fig. 30 represents the outline of a common suction-pump. It consists of a cylinder, furnished with a piston A, made to fit air-tight. In this piston there is a valve opening upwards, but here indicated as closed. When the piston is raised, the air under it is rarefied more and more at each stroke, and the pressure of the air upon the surface of the water on the outside of the tube forces the fluid into it. The valve B is at the same time opened upwards, and the water, after several strokes, rushes in above it. When the upward stroke of the piston is complete, it is again depressed—the water passes through the valve in

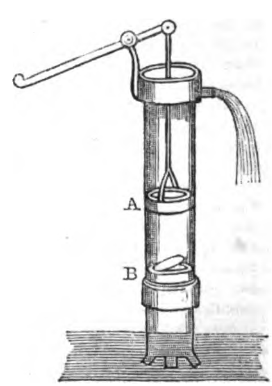

Fig. 30.

the piston, and on the next stroke it is discharged at the spout.

In this form of pump, the greatest height to which the water can be raised, counting from the level of the well to the bottom valve, is, in theory, thirty-four feet, when the level of the mercury in the barometer is thirty inches. In practice, however, owing to the imperfect vacuum, the height never reaches the above, the limit being more usually twenty feet. The space between the piston and the bottom valve should be as small as possible, to allow little space for the collection of vapour or air, this being more especially desiderated in force-pumps which are used to pump hot water.

The height to which water can be raised above its level, can be greatly increased by the use of the force-pump. In fig. 31, which is a diagram illustrative of the

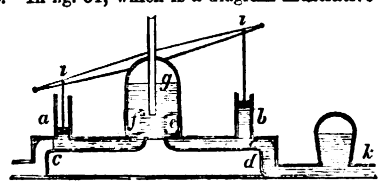

Fig. 31.

mechanism of a fire-engine, in which force-pumps are used to raise the water to the height required, the pumps are two in number, *a* and *b*, both being worked by the lever *ll*. The pistons are solid, and work water-tight in the pumps; valves *c*, *d*, are connected with the pipes which lead to the water to be pumped up; other valves, *f* and *e*, are placed at the ends of the pipes which lead to the air-chamber *g*. All these valves open upwards. On the piston *b* rising, the water flows through the valve *d*, forced by the atmospheric pressure, and fills the space below the piston. The depression of the lever *ll* at the end near *a* forces the piston of *a* down the pump, closes the valve *c*, and forces the water through the valve *f* into the air-chamber *g*. The water is prevented leaving this through the other pipe leading from *b* by the closing of the valve *e*. The air which is compressed in the upper part of the chamber *g* presses upon the surface of the water contained in it, and causes the water to rush out from the orifice of the pipe in a nearly continuous stream.

It is clear that, both in the suction-pump and in the force-pump, the motion of the water is intermittent; which circumstance causes a great waste of power. It is calculated that in the majority of lifting and forcing-pumps, from 55 to 80 per cent. of the power is expended in giving a velocity to the water in the first instance, which velocity has to be suddenly checked, so that it is not available as working-power. The evil of the intermittent nature of the action is aggravated by a variety of causes:—First, the small size and faulty construction of the valves. By increasing the size of these, the sudden change in the section and velocity of the stream would be avoided. As the variation of the velocity is dependent upon the ratios of the suction-pipe and force-pipe to the barrel, attention should be paid to attain to an approximation of these. This want of due proportion is a second cause of loss of power. The third cause stated is the neglect to make the extremity of the suction-pipe where the water enters it such as to render the contraction of the vein as small as possible. In HYDRAULICS, we have seen that the discharge of water from a pipe depends upon the shape of the orifice. It has been found that an equal effect is obtained by attending to the shape of the orifice at which it enters. By expanding, then, the lower extremity of the suction-pipe where it enters the water into the shape of a cone, the diameter of the wider end being 1·2 times that of the narrower, the contraction of the vein may be nearly destroyed. By similarly expanding the discharging orifice, a discharge will be obtained greater than that due to the section of the pump. A fourth cause of loss is the neglect of the shape of the pipes where they unite with the *barrel*. The fifth is a very prolific cause of loss, and one which is by no means generally known or attended to: it is working force-pumps with too great a velocity. Space prevents us from going into an explanation of this cause of loss of power. The results of the investigation, however, prove that 'the proportions of a pump, to be worked by a given motive power, should be such, that the power to be expended at every stroke may just bring the water raised to rest at the end of each stroke.' The Jury Report of the Great Exhibition on pumps, from which we have compiled the above, has the following: 'A remedy for some of these evils in the working of a pump, has been sought in the application to it of a second air-vessel communicating with the suction-pipe immediately below the barrel, or with the top of the suction-pipe and the bottom of the barrel. The commencement of each stroke is eased by a supply of water from this air-chamber to the space beneath it. The influx of the water into that space is aided by the pressure of the condensed air in the air-chamber; and when the stroke is completed, the state of condensation of this air is, by the momentum of the water in the suction-pipe, restored, causing it to rush through the passage by which that pipe communicates with the air-chamber.' In fig. 31, *k* shews the position of the second air-chamber in the suction-pipe.

Centrifugal Pumps.—The evil of an intermittent current, to which common pumps are liable, is escaped in centrifugal pumps, which may be noticed here, though not pneumatic machines. A centrifugal pump is a hollow wheel traversed by vanes or arms curved or straight, and which is made to revolve rapidly; the water entering at the axis is put in rapid rotation, and is expelled at the circumference by its centrifugal force. The water is led to the wheel by a pipe which answers to the suction-pipe of a common pump; the wheel, however, is frequently made to revolve in the water which it has to raise—as in drains, lakes, &c. If the water is expelled from the wheel into a closed receptacle like that of the fire-engine, it forces a continuous stream up a pipe. There are two classes of centrifugal pumps—those in which the arms are curved, and those in which they are straight. Experience in the working of both kinds has amply proved that by using curved arms the greatest effect is obtained. In fig. 32

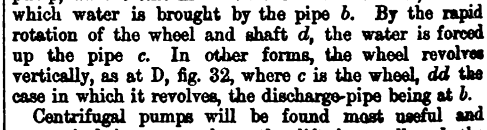

Fig. 32.

A shews a pump with flat, and B one with curved, arms or vanes. The wheel in some forms revolves horizontally, as at C, in fig. 32, which is a sketch of Bessemer's pump, *aa* the case in which the wheel revolves, and to which water is brought by the pipe *b*. By the rapid rotation of the wheel and shaft *d*, the water is forced up the pipe *c*. In other forms, the wheel revolves vertically, as at D, fig. 32, where *c* is the wheel, *dd* the case in which it revolves, the discharge-pipe being at *b*.

Centrifugal pumps will be found most useful and economical in cases where the lift is small and the quantity of water to be raised considerable. As tidal pumps, they are particularly useful, for the lower the lift the greater the quantity discharged at the same speed. Since the level of tidal water is constantly changing, a greater amount of work will be obtained than by the use of ordinary pumps, for these can only raise their cubical contents, no matter what the lift. Centrifugal pumps are not only easily fitted up, but they are not apt to get out of repair, from the absence of valves and

complicated mechanism. This feature is also advantageous in another way, stones and other obstructions being easily passed through without damage.

Syphon.—The action of the syphon will be readily understood from the principles already illustrated. It is simply a bent tube, with one end inserted in a liquid, as represented in fig. 33. To begin the action, the air is withdrawn from the tube by means of the mouth or a syringe, when the liquid enters and fills it, as in other cases of suction. When the suction is stopped, there are two forces acting on the liquid in the tube—the pressure of the atmosphere on the liquid in the vessel, forcing it in the direction from C towards B and A, and the pressure at A, forcing it in the opposite direction. These two pressures are of themselves equal, and when the lengths of the columns of liquid in the two legs are equal, there is no flow; but when one column, as AB, is longer than the other, its weight destroys the balance, and produces a flow towards itself. The length of the column BC, is counted from the level of the liquid, not from the mouth of the tube. It is clear that the height of B above C can never exceed thirty-four feet.

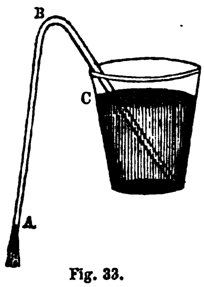

Fig. 33.

OTHER EFFECTS OF ATMOSPHERIC PRESSURE.

Pressure on the Human Body.—The body of a man has, on an average, a surface of about 2000 square inches. At the rate, then, of fifteen pounds to the square inch, the whole pressure which a person of an ordinary size sustains on the surface of his body is 30,000 pounds, or nearly fourteen tons. It gives a wrong notion of this pressure to speak of it as a load. It has, on the contrary, a buoyant effect, and makes a man lighter, or press less on the earth, than he would without it (see below). Air presses on all sides of a body immersed in it. It is therefore a compressing or crushing force, and does not at all act as a weight. The reason why this compression is not felt, and does not in effect squeeze the body into less bulk, is that there is an equal pressure *outwards* at all parts. In fig. 1, a force of a pound pressing in the plug *a*, is felt as an equal force pressing out the plug *b*. Now, the blood and other liquids in the body, though contained in tubes, transmit pressure through all their ramifications, as the water in the box B does through its mass; and the direct pressure of the atmosphere on any spot of the outer surface, tending to squeeze in the sides of the tubes containing the fluids, is met by an equal pressure on the part of the fluids, to force out the sides of the vessels, which outward pressure itself is caused by the atmosphere pressing on other parts of the system.

We are as little sensible, in ordinary circumstances, of this outward pressure of the fluids on the vessels of the body, as we are of the compressing force of the atmosphere. But it makes itself felt whenever the external pressure is removed from any part, as in the familiar act of sucking the finger, or more strikingly in the operation of cupping. A small bell-shaped glass, in which the air has been rarefied by burning a slip of paper, or by other means, is suddenly applied to a flat surface of the body. The small portion of air under the glass, as it cools, presses with diminished force on the surface of the skin; and the fluids within, released from the usual check, swell out the vessels and skin, and if a wound has been made with a lancet, the blood is forced out. When the usual pressure of the atmosphere is much diminished over the whole body by ascending great heights, uneasy sensations are often felt, occasioned most likely by air contained in the liquids and in cavities of the solid parts of the body, seeking to expand.

Boy's Sucker.—A boy's sucker affords a good illustration of the operation of atmospheric pressure. A piece of moist leather is pressed against a smooth stone, so as to exclude all air from between them. They are now held together with a force of fifteen pounds on the square inch. By beginning at the edge, they could be separated easily, because the air fills up the interstice as it is formed. But if a string is attached to the middle of the leather, as represented in fig. 34, and pulled upwards, separation is resisted. If, by a strong pull, a portion—say a square inch—of the leather is raised up, there is a vacuum under it, and the weight of the atmosphere on the upper side of that inch has to be borne up by the hand. With regard to the stone, again, we have to consider that before the vacuum was formed, the atmospheric pressure on its under side was exactly equal to that on its upper side; the two counteracted one another, and produced no effect, either in increasing or lessening the weight of the stone. But the effect of the vacuum is to remove the pressure from an inch of the upper surface, so that on the square inch of the under surface opposite the vacuum there is an upward pressure of fifteen pounds which is not counteracted; and by this amount of force the stone is pushed up. If not too heavy, it may thus be lifted by means of the sucker. Correctly speaking, the sucker does not lift the stone; it only lifts the weight of a column of the atmosphere from off the stone, and thus allows the remaining atmospheric pressure to push it up.

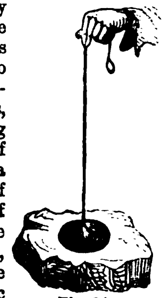

Fig. 34.

The feet of flies, and some other insects, are formed on the principle of the sucker; and by this means they can walk on the ceiling of a room, or on an upright smooth pane of glass. When deprived of the extremities of its legs, on which the apparatus for adhesion is situated, a fly can no longer climb an upright surface, or walk on a roof with its back downwards, though it can walk on the surface of a table without apparent difficulty. Limpets and other testaceous animals adhere to rocks by causing a partial vacuum within their shells, which they accomplish by contracting themselves into less bulk.

Bird-cage Fountain—Vent-peg, &c.—It is surprising at first sight, that in ink-bottles of the kind represented in fig. 35, and in bird-cage fountains, which are of much the same make, the liquid should stand as high as the top at A without flowing out at C. But the very same cause sustains it that sustains the column of mercury in fig. 26, and keeps it from flowing out at C—the atmospheric pressure, namely, on the surface at C, while the top at A is close, like the top of the tube in fig. 26. The greater width of the bottle makes no difference, the pressure of liquids being not as width, but as depth (see page 226.) The atmospheric pressure on C would be able to keep up the liquid in the bottle till it reached the height of thirty-three feet, or thereby. The ink is introduced into a bottle of this kind by inclining it over, and pouring in gradually at C. When the ink in the tube CB sinks down by use to the level of the horizontal communication, a bubble of air gets in, and rising to the top at A, fills part of the space, and forces down a portion of ink into C.

Fig. 35.

On the principle now explained, if the lid of a tea-pot were quite close, so as to exclude the pressure of the atmosphere from the top of the liquid within, the liquid

could not be poured out. It is for this reason that in drawing liquor from an opening in the lower part of a cask, there must be a vent-peg at the top to admit air.

Every one knows that when a full bottle is turned mouth downward, the liquid cannot flow out but in proportion as air can pass in. It is instructive to mark the difference between the case of a common bottle inverted, and the case of the ink-bottle, fig. 35. The atmosphere pressing upon the downward surface of the liquid in the neck of the bottle, prevents it from *descending* as strongly, as it prevents the ink from *ascending* in the tube at C. But air being lighter than the liquid, bubbles of it enter the downward surface, and ascend to the top, where their elastic pressure overcomes that of the outward air, and forces down the liquid; while, before a particle of air could get to the top of the ink-bottle, it would have to *descend* through the liquid in the tube C, which the comparative specific gravity of the two fluids prevents.

A liquid will not flow at all even from a downward opening in a vessel close at the top, provided the air be prevented from entering the surface in bubbles, and rising up through it. If we conceive a thin disk of caoutchouc inserted in the lower end of the tube, fig. 25, so as to slide up and down without resistance, and yet be air-tight, the tube might be lifted from the cistern without the mercury falling out. A simpler way of illustrating the same principle is the following :—Take a common wine or ale glass, with as even edges as possible, fill it brimful with water, and on the top lay a round disk of smooth stiff writing-paper, rather larger than the mouth of the glass. Above this, place a book, and pressing it down, invert the whole, so that the glass shall stand on the book with the mouth downwards, and perfectly horizontal. In this position, the glass may be lifted up from the book with the paper adhering to its mouth, and the water hanging in it apparently without support.

BUOYANCY IN AËRIFORM FLUIDS.

The fundamental law in this is exactly the same as in liquids (see page 229). A body in air displaces its own bulk of the air, and is borne up with a force equal to the weight of the air so displaced. If the body's own weight is less than this, it must rise up, as a piece of cork does in water; if greater, the body only loses a portion of its weight, as a stone in water.

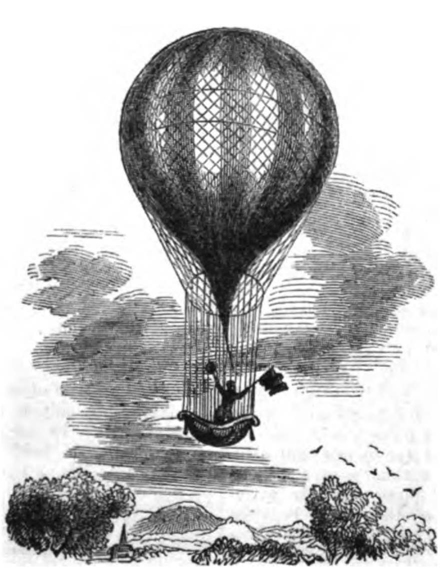
In weighing bodies in air, the fact that the air deprives them of part of their weight, does not interfere with the accuracy of the process so long as the substance is nearly of the same density as the weight against which it is balanced, because then both are equally affected. But where there is great difference of density, it leads to sensible error. A pound of feathers—as it is sometimes paradoxically stated—is heavier than a pound of lead; that is, it contains more matter. If a quantity of feathers occupying a cubic foot of space, were balanced in a vacuum against a piece of metal, the balance would be destroyed on taking them into the air. The feathers would lose above an ounce—the weight of a cubic foot of air—the metal would lose only a few grains.

BALLOONS.

Solid bodies cannot of themselves float in air, being all heavier than an equal bulk of it; but by enclosing air rarefied by heat, or a light gas, such as hydrogen, in a bag, it may be made to buoy up more or less solid matter along with it. Such a contrivance is a balloon. A soap-bubble blown from hot water with warm air, is the simplest form of balloon, but soon loses its buoyancy by cooling; if blown with hydrogen, it continues ascending till it bursts. A body floating in air rises till it arrives at a stratum of the atmosphere whose density is the same as its own.

A balloon is a bag made of varnished silk, and surrounded by a net-work, from which a car is suspended. Balloons were originally filled with heated air, and had a fire suspended in the opening below to keep up the temperature. So far as lightness is concerned, hydrogen would be the best gas for the purpose; but, from its cheapness, common coal-gas is generally employed, whose density is rather more than half that of air.

The air contained in a room fifty feet long, thirty wide, and twenty high, weighs upwards of a ton. A balloon of this capacity (30,000 cubic feet) would thus displace a ton of air, while the gas contained in it weighed only half a ton; it would therefore ascend with a force equal to the difference, or half a ton after deducting, of course, the weight of the silk, and other parts of the apparatus. The greatest elevation ever reached in a balloon was by Gay Lussac; the barometer sunk to 12 inches, and the height was computed at 23,000 feet, or 4⅓ miles. The ascent and descent of a balloon can be regulated by means of valves for allowing gas to escape, and of ballast which can be thrown out at pleasure; but the impossibility of guiding the horizontal motion, renders the art of *aërostation*, as it is called, only a matter of amusement.



OPTICS—ACOUSTICS.

OPTICS.

THE term *Optics* is derived from a Greek word which signifies *seeing*, and applies to that branch of natural philosophy which treats of the phenomena of *light* and *vision*. Of the precise character of light there are various theories, but none which admits of actual demonstration or proof. By some it has been described as consisting of very minute particles or molecules, which are thrown off from what are called luminous bodies in all directions, and with immense velocity; while others consider it as the effect of an undulation or vibration produced by luminous bodies in the thin and elastic medium which is interposed between them and the seat of our vision—this vibration producing an effect upon our organs, which we recognise as light, in a manner analogous to the impression of sound on the ear caused by vibrations of the atmosphere. The latter is called the *undulatory* theory of light; and the former—in which light is supposed to consist of *material* particles—the theory of *emission*.* Whatever may be the cause or absolute nature of light, we know it is a property of luminous bodies which enables us to see the luminous objects themselves, as well as others in their vicinity, and that its absence produces darkness.

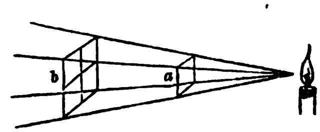
All visible bodies may be divided into two classes—*self-luminous* and *non-luminous*. Under the first head are comprised all those bodies which possess in themselves the property of exciting the sensation of light or vision, such as the heavenly luminaries, terrestrial flames of all kinds, phosphorescent bodies, and those bodies which shine by friction or by being heated. Under the second class we recognise such bodies as have not of themselves the power of throwing off particles or undulations of light, but which possess the property of reflecting the light which is cast upon them from self-luminous bodies. A non-luminous body may thus, by reflection, receive light from another non-luminous body, communicate it to a third, and so on. All reflected light, however, is inferior in brilliancy to that which comes direct from a self-luminous body.

Anciently, it was believed that light was propagated from the sun and other luminous bodies instantaneously; but the observations of modern inquirers have shewn that this was an erroneous hypothesis, and that light, like sound, requires a certain time to pass from one part of space to another, though the velocity of its motion is truly astonishing, as has been manifested in various ways. Astronomers have proved, by observing the eclipses of Jupiter's satellites when that planet is nearest and when it is furthest from the earth, that light moves from the sun to the earth—a distance of 95,000,000 miles—in seven and a half minutes, or about 200,000 miles during a single vibration of a pendulum. So prodigiously great is this velocity, that, as far as any common observation is concerned, light may be regarded as perfectly instantaneous in its action.

* The theory of emission was devised by Newton, and for a long time it was thought to explain the facts better than any other. It is not necessary to suppose that the particles succeed each other closely, so as to crowd the whole of space with a luminous stream. It is found that a single impression of light will remain on the eye for the eighth of a second, and therefore if eight particles fell upon it every second, there would be a permanent impression produced. But in the eighth of a second a ray passes through 25,000 miles, so that if one particle followed another at this distance, constant light would be maintained, and the shower would be so thin and scattered, as to allow room enough for all the innumerable crossings of luminous rays. At present, however, there are many phenomena which cannot be explained by this theory, and are found more consistent with the undulatory hypothesis.

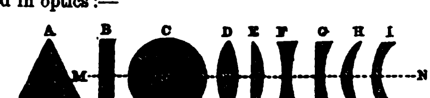
Light proceeds in a straight direction from the luminous body which produces it, towards the part or situation against which it is permitted to act. In consequence of this directness, a shadow or darkened spot is observable behind any opaque object presented to the light. During night, we are in the earth's shadow; and this shadow reaches so far beyond us into space, that when the moon plunges into it in her course, she undergoes an eclipse.

In proportion as light advances from its seat of production, it diminishes in intensity. The ratio of diminution is agreeable to that which governs physical forces—that is, the intensity of the light will diminish as the square of the distance increases, or at the rate of 1, 4, 16, &c. But in proportion as we lose in intensity, we gain in volume; the light is the weaker the further it is from the candle, but it is filling a wider space. Thus, if a board *a*, a foot square, be placed at the distance of one foot from a candle, it will be found to hide the light from



another board *b*, of two feet square, at the distance of two feet from the candle. Now, a board of two feet square is just four times as large as one of one foot square, and therefore the light at double the distance being spread over four times the surface, has only one-fourth the intensity.

Preliminary to any further exposition of the nature and action of light, we offer the following definitions of terms:—Any parcel of rays passing from a point is called a *pencil* of rays. By an optical *medium* is meant any pellucid or transparent body—as, for example, air, water, or glass—which suffers light to pass through it. *Parallel rays* are such as move always at the same distance from each other. If rays continually recede from each other, they are said to *diverge;* if they continually approach each other, they are said to *converge.* The point at which converging rays meet, is called the *focus;* the point towards which they tend, but which they are prevented from coming to by some obstacle, is called the *imaginary focus.* When rays, after passing through one medium, on entering another medium of different density, are bent out of their former course, and made to change their direction, they are said to be *refracted;* when they strike against a surface, and are sent back again from the surface, they are said to be *reflected.* A *lens* is a glass ground into such a form as to collect or disperse the rays of light which pass through it. These are of different shapes, and thence receive different names. The following figures individually represent sections of the variously shaped lenses and other glasses used in optics:—



A is a triangular stalk of pure glass, of which we have here a cross sectional or end view, and which is called a *prism;* each side of the prism is smooth. B is a section of a piece of plane glass, with sides parallel to each other. C is a sphere or ball of glass, and consequently

is convex on all parts of its surface. D is a piece of glass convex, or bulging on its two sides, and is called a *double convex lens.* It is this kind of lens which is used for magnifying objects, in spectacles, telescopes, and other instruments. E is a *plano-convex lens,* flat or planed on one side, and convex on the other. F is a *double concave lens,* or glass hollowed on each side. G is a *plano-concave lens,* or planed on one side, and concave on the other. H is a *meniscus,* or lens convex on one side and concave on the other, both surfaces meeting, and of which we have an example in watch-glasses. I is an example of the *concavo-convex lens,* in which the surfaces disagree, or do not meet when continued. In all these lenses, an imaginary line, represented by MN, and passing through the centres of the surfaces, is called the *axis.*

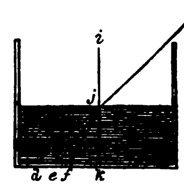
In treatises on optics, it is customary to divide the subject into two sections, under the heads Dioptrics and Catoptrics. The term *dioptrics* is compounded of two Greek words signifying to *see through,* and refers to the transmission of rays of light through transparent bodies, and the laws which such rays observe. *Catoptrics* is also from the Greek, and signifies to *see from* or *against:* it refers to the reflection of light from surfaces, and the formation of images by means of mirrors and other objects.

REFRACTION OF LIGHT.

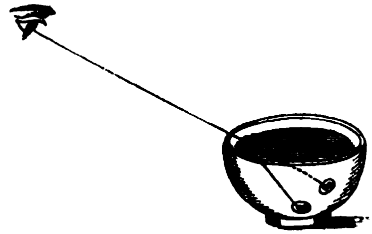
Refraction, as already mentioned, is the bending of rays of light from the course they formerly pursued. If the rays, after passing through a medium, enter another of a different density, perpendicular to its surface, they are not refracted, but proceed through this medium in their original direction. For instance, if the sun's rays were to strike upon the surface of a river at right angles, or perpendicularly, to its surface, they would go straight to the bottom, and the line they observed in the air would be continued in the water. But if they enter obliquely to the surface of a medium either denser or rarer than what they moved in before, they are made to change their direction in passing through that medium; that is, they are refracted.

The mode of the refraction depends on the comparative density or rarity of the respective media. If the medium which the rays enter be denser, they move through it in a direction nearer to the perpendicular drawn to its surface. On the contrary, when light passes out of a denser into a rarer medium, it moves in a direction further from the perpendicular. This refraction is greater or less—that is, the rays are more or less bent, or turned aside from their course—as the second medium through which they pass is more or less dense than the first. To prove this in a satisfactory way, take an upright empty vessel into a darkened room, which admits but a single beam of light obliquely through a hole in a window-shutter. Let the empty vessel stand on the floor, a few feet in advance of the window which admits the light, and let it be so arranged that, as the beam of light descends towards the floor, it just passes over the top of the side of the vessel next the window, and strikes the bottom on the side furthest from the window. Let the spot where it falls be marked. Now, on filling the vessel with water, the ray, instead of striking the original spot, will fall considerably nearer the side towards the window. And if we add a quantity of salt to the vessel of water, so as to form a dense solution, the point where the ray strikes the bottom will move nearer to the window. In like manner, if we draw off the salt water, and supply its place with alcohol, the beam of light will be still more highly refracted; and oil will refract yet more than alcohol.

Let the annexed oblong figure represent a vessel half filled with water, and R the ray of light which may be expected to pass through it to the bottom at *d.* The direction of the ray is perfectly straight until it enters the water at *j,* when, instead of proceeding in a straight line to *d,* it is bent from its course, and compelled to strike the bottom of the vessel at *e.* If oil instead of water had been used, the ray would have been still more bent, and have reached the bottom at *f.* If the ray had been sent directly downwards, as from *i* to the surface of the water at *j,* it would not have been refracted, but have proceeded straight to the bottom at *k.*



The following simple experiments are well known:—Take an empty basin and place it on a table, then lay a shilling at the bottom of the basin, in such a



position that the eye of the observer will not see it. Now fill the basin with water, and the shilling, though lying unmoved, will come completely into sight. The explanation of this phenomenon is, that the ray of light producing vision in the eye is bent on emerging from the water, and has all the effect of conveying our sight round a corner. In like manner, the refractive power of water is observable when we thrust a straight stick or instrument into it, on aiming at any object. We see that the stick seems to be bent, and fails in reaching the point which we desired it should. On this account, the aim by a person not directly over a fish must be made at a point apparently below it, otherwise the weapon will miss by flying too high. Persons who spear salmon in rivers require to calculate upon this refractive power in taking their aim.

With regard to the refractive power of transparent substances or media, the general rule, with certain limitations, is, that it is in proportion to the densities of the bodies. It increases, for instance, from the most perfect vacuum which can be formed, through air, fresh water, salt water, glass, and so on. Tables of the refractive powers of substances most interesting in optics will be found in Brewster's *Optics.* From these it would appear that substances which contain fluoric acid have the least refractive power, as inflammable ones have the greatest. As to the cause of refraction, or the way in which the bending of the rays is brought about, explanations are given both on the undulatory theory and on that of emission, but they are of too abstruse a nature to be introduced here.

The refraction of rays of light is observable in the case of common window-glass. The two sides of a pane not being perfectly parallel to each other, bodies seen through it appear as if distorted; and as the obliquities in the glass are very various, the distortions are equally grotesque and numerous. Some windows are purposely ground on the surface, to produce universal and minute refraction; and thus so great a confusion is introduced among the rays, that objects are not distinguishable through the glass. When the obliquities on the surface of one side of a piece of glass stand distinct from each other, so as to admit of refraction in a clear and distinguishable manner, then each obliquity affords a separate view of an object on the opposite side, and thus an object seems to be multiplied as many times as there are obliquities.

The refraction of light is observable on a great scale in relation to our atmosphere. The rays of the sun, on reaching the confines of the atmospheric fluid which envelops the earth, enter a medium of greater density than that which they have previously been pursuing, and consequently are refracted or bent. One obvious effect of this is, that we never see the sun in the actual position which he occupies. He is always less or more, in relation to our eyes, what the shilling is said to be in the above experiment with the basin of water. This is peculiarly the case in the morning, when his earliest rays reach our eyes; entering a denser medium, these rays bend round to meet our vision, and we actually see the body of the sun a few minutes before he has risen above the horizon—like the shilling in the basin, we see him round a corner. In proportion as the sun approaches the zenith, the refraction diminishes; and as he recedes towards setting, it increases. So considerable is it in the hazy atmosphere of the evening, that we retain a sight of his disk after he has set.

From these explanations, it will appear that the directness of our vision is at all times liable to be disturbed by atmospheric conditions. So long as the atmosphere betwixt our person and the object we are looking at is of the same density, we may be said to see in a straight line to the object; but if by any cause a portion of that atmosphere is rendered less or more dense, the line of vision is at once refracted or bent from its course. A thorough comprehension of this simple truth in science has banished a mass of superstition. It has been found that, by means of powerful refraction, objects at a great distance, and round the back of a hill, or considerably beneath the horizon, are brought into sight. In some countries, this phenomenon is called the *mirage*. The following is one of the most interesting and best authenticated examples:—In a voyage performed by Captain Scoresby in 1822, he was able to recognise his father's ship, when below the horizon, from the inverted image of it which appeared in the air. 'It was,' says he, 'so well defined, that I could distinguish by a telescope every sail, the general rig of the ship, and its particular character; insomuch that I confidently pronounced it to be my father's ship the *Fame*, which it afterwards proved to be; though, on comparing notes with my father, I found that our relative position at the time gave our distance from one another very nearly thirty miles, being about seventeen miles beyond the horizon, and some leagues beyond the limit of direct vision. I was so struck by the peculiarity of the circumstance, that I mentioned it to the officer of the watch, stating my full conviction that the *Fame* was then cruising in the neighbouring inlet.'

A curious phenomenon of this kind was seen by Dr Vince, on the 6th of August 1806, at 7 P.M. To an observer at Ramsgate, the tops of the four turrets of Dover Castle are usually seen over a hill between Ramsgate and Dover. Dr Vince, however, when at Ramsgate, saw the whole of Dover Castle, as if it had been brought over and placed on the Ramsgate side of the hill. The image of the castle was so vivid, that the hill itself did not appear through the image.

In the sandy plains of Egypt, the mirage is seen to great advantage. These plains are often interrupted by small eminences, upon which the inhabitants have built their villages, to escape the inundations of the Nile. In the morning and evening, objects are seen in their natural form and position; but when the surface of the sandy ground is heated by the sun, the land seems terminated at a particular distance by a general inundation: the villages which are beyond it appear like so many islands in a great lake, and between each village an inverted image of it is seen.

That the phenomena of the mirage are produced by variations in the refractive power of the atmosphere, can be proved by experiment. If the variation of the refractive power of the air takes place in a horizontal line perpendicular to the line of vision—that is, from right to left—then we have the lateral mirage; that is, an image of a ship may be seen on the right or left hand of the real ship, or on both, if the variation of refractive power is the same on each side of the line of vision. If there should happen at the same time both a vertical and a lateral variation of refractive power in the air, and if the variation should be such as to expand or elongate the object in both directions, then the object would be magnified, as if observed through a telescope, and might be seen and recognised at a distance at which it would not otherwise have been visible. If the refractive power, on the contrary, varied so as to contract the object in both directions, the image of it would be diminished, as if seen through a concave lens.

In order to represent artificially the effects of the mirage, Dr Wollaston suggested the viewing of an object through a stratum of spirit of wine lying above water in a crystal jar, or a stratum of water lying above one of sirup. These substances, by their gradual incorporation, produce a refractive power diminishing from the spirit of wine to the water, or from the sirup to the water: so that, by looking through the mixed or intermediate stratum at a word or object held behind the bottle which contains the fluids, an inverted image will be seen. The same effect, it has been shewn, may be produced by looking along the side of a red-hot poker at a word or object ten or twelve feet distant. At a distance less than three-eighths of an inch from the line of the poker, an inverted image is seen, and within and without that, an erect image.

The method employed by Sir David Brewster to illustrate these phenomena, consists in holding a heated iron above a mass of water bounded by parallel plates of glass; as the heat descends slowly through the fluid, we have a regular variation of density, which gradually diminishes from the bottom to the surface. If we now withdraw the heated iron, and put a cold body in its place, or even allow the air to act alone, the superficial stratum of water will give out its heat, so as to produce a decrease of density from the surface to a certain depth below it. Through the medium thus constituted, the phenomena of the mirage may be seen in the most interesting manner.

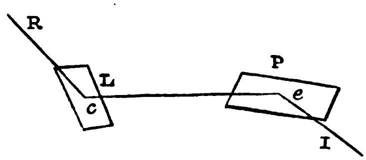
Double Refraction.

In the preceding part of this section, we have considered a single ray of light, reflected or transmitted through the substance of a transparent body, as leaving it in the same way in which it came into contact with it—namely, in a single pencil or ray. But there are a great many bodies which have the power of breaking the pencil of light incident upon their surfaces into two separate parts or pencils, more or less inclined to one another, according to the nature and state of the body, and according to the direction of the incident pencil. This is called *double refraction*, and the bodies which produce it are called doubly refracting bodies or crystals. They are very numerous, and include all salts and crystallised minerals not having the primitive forms of the cube, the regular octohedron, and the rhomboidal dodecahedron. Of all known bodies, the Iceland spar, or rhomboidal carbonate of lime, shews the fact with the greatest certainty; and as it is a mineral easily procured, it has been generally used in experiments upon this subject. Its crystals are of a rhomboidal form, having six acute solid angles, and two obtuse. Double refraction of light is employed to advantage in some kinds of lighthouses; and those who wish to investigate its nature and properties, may be referred to advanced treatises on the subject.

Polarisation of Light.

A ray of light, after reflection at a certain angle from the surface of any body, is found to have undergone a remarkable change in its nature. To the unaided eye, it

appears to possess only the attributes of ordinary light; but when certain tests are applied to it, it is found to have acquired new properties. Thus, let I*e* be a ray

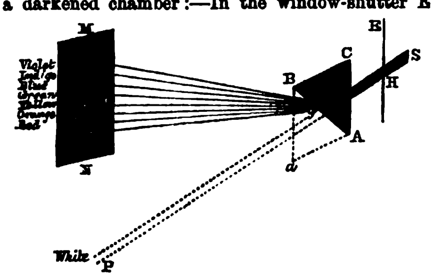


incident at an angle of 33° on a plate of glass P, and let it be reflected in the line *ec* to another plate L, so situated that the angle of incidence on it is also 33°, and that the new plane of incidence *ec*R coincides with the first I*ec*; then the light will be reflected from the second plate in the ordinary way. But if the new plane of incidence *ec*R is perpendicular to the former, there is *no light reflected.* The ray *ec* is therefore quite different from ordinary light. The ray *ec*, reflected at the first incidence, is said to be *polarised;* and the angle at which this effect happens is called the angle of *polarisation.* When light is transmitted through certain crystals, called double-refracting crystals, it is found to be similarly polarised. For further details on this part of the subject, we must also refer to works of higher scope than the present.

Colour by Refraction.

One of the most remarkable phenomena attending refraction is, that the rays of light, which seem to us to be white, may be separated into rays of various colours. It will be obvious that light has the effect of representing colours, where no colour substantially exists, by noticing the glancing and varied hues on irregular surfaces of glass, ice, or other crystallised substances.

The proper method of analysing the rays of light, and discovering into what colours they may be resolved, is to procure a prism, and perform the following experiment in a darkened chamber:—In the window-shutter E of



a darkened room, make a small hole H, through which admit a beam of the sun's light S, which, when nothing is interposed, will proceed in a straight line to P, and form a luminous white spot. If we now interpose a prism BAC, whose refracting angle is B*a*C, so that the beam of light may fall on its surface CA, and emerge at the same angle from its second surface BA, in the direction *g*G, and if we receive the refracted beam on the opposite wall, or on a white screen MN, 'we should expect,' says Sir David Brewster, 'from the principles already laid down, that the white beam which previously fell upon P would suffer only a change in its direction, and fall somewhere upon MN, forming there a round white spot exactly similar to that at P. But this is not the case. Instead of a white spot, there will be formed upon the screen MN an oblong image KL of the sun, containing seven colours—namely, red, orange, yellow, green, blue, indigo, and violet—the whole beam of light diverging from its emergence out of the prism at *g*, and being bounded by the lines *g*K, *g*L. This lengthened image of the sun is called the *solar* or *prismatic spectrum.* If the aperture H is small, and the distance *g*G considerable, the colours of the spectrum will be very bright. The lowest portion of it at L is a brilliant red. This red shades off by imperceptible gradations into orange, the orange into yellow, the yellow into green, the green into blue, the blue into a pure indigo, and the indigo into a violet. No lines are seen across the spectrum thus produced; and it is extremely difficult for the sharpest eye to point out the boundary of the different colours. Sir Isaac Newton, however, by many trials, found the lengths of the colours to be as follow, in the kind of glass of which his prism was made:—Red, 45; orange, 27; yellow, 40; green, 60; blue, 60; indigo, 48; violet, 80—Total length, 360.'

These colours are not equally brilliant. At the lower end L of the spectrum, the red is comparatively faint, but grows brighter as it approaches the orange. The light increases gradually to the middle of the yellow, where it is brightest; and from this it gradually declines to the upper or violet end K of the spectrum, where it is extremely faint.

From the phenomena which we have now described, Sir Isaac Newton concluded that the beam of white light is compounded of light of seven different colours, and that for each of these different kinds of light, the glass of which his prism was made had different indices—that is, measures of refraction; the index of refraction for the red light being the least, and that of the violet the greatest.

By means of a second prism placed behind a hole in the screen MN, opposite the centre of each coloured space, Sir Isaac Newton refracted the light a second time. In this case it was not drawn out into an oblong image as before, and was not refracted into any other colour than that which formerly belonged to each particular ray. Hence this great philosopher concluded that the light of each particular colour possessed the same index of refraction; and he termed such light homogeneous—that is, of the same kind, or simple; white light being regarded as heterogeneous—that is, of different kinds, or compound.

By various experiments, Sir Isaac proved that all the colours, when again combined, formed or recomposed white light. Indeed, the doctrine may be illustrated by mixing together, in proper proportions, seven colours as like those of the spectrum as can possibly be got. By their union a grayish white is formed, for powders of the exact tint as those of the spectrum cannot be obtained. It may also be proved in this manner:—Let a circle of paper be divided into sections of the same size, and coloured like the spaces in the spectrum, and placed upon a humming-top, which is made to revolve rapidly; the effect of all the colours, when combined, is to produce a grayish white.

'All transparent substances, in bending light,' observes Dr Arnott, 'produce more or less of the separation of colour; but it is an important fact, that the quality of merely bending a beam, or of *refraction*, and that of dividing it into coloured beams, or of *dispersion*, are distinct qualities, and not having the same proportion to each other in different substances. Newton, from not discovering this, concluded that a perfect telescope of refraction could never be made; he supposed that the bent light would always become coloured, and so render the object indistinct. We now know, however, that by combining two or more media, we may obtain bending of light without dispersion—thus, by opposing a glass which bends five degrees and disperses one degree, to another glass which bends three degrees and disperses one, the opposing dispersions will just counterbalance each other, while the two degrees of excess of bending will remain to be applied to use.' It is on this principle that achromatic lenses are constructed.

It having been found, by the experiments of Newton and others, that none of the seven colours of the solar spectrum could be broken by the prism into new colours, the theory was in some measure established that there

were *seven* primitive colours. In time, however, practical men discovered that there were only *three* simple or homogeneous colours, and that all others resulted from them. These three primitive colours were *red*, *blue*, and *yellow*. On this doctrine we give the following extract from a treatise on the *Laws of Harmonious Colouring*, by Mr D. R. Hay (Edinburgh):—

'Although this theory (that of there being only three primitive colours) was not set up in opposition to that of the natural philosophers, but seemed only to be established in a practical point of view, neither was it supported by any scientific experiments; yet it appeared to me more consistent with the general simplicity of nature, and I could not believe that she required seven homogeneous parts to produce what art could do by three. For instance, an artist can make all the colours, and indeed a correct representation of the prismatic spectrum (so far as the purity of his materials will allow), with three colours only; while, according to the theory of Sir Isaac Newton, seven simple or homogeneous colours were employed to produce the real one.

'The following discovery, made by Buffon, and illustrated by succeeding philosophers, helped to strengthen me in the conviction that the scientific theory might, like that of the practical artist, be reducible to three simple or homogeneous parts. If we look steadily for a considerable time upon a spot of any given colour, placed on a white or black ground, it will appear surrounded by a border of another colour. And this colour will uniformly be found to be that which makes up the triad: for if the spot be red, the border will be green, which is composed of blue and yellow; if blue, the border will be orange, composed of yellow and red; and if yellow, the border will be purple—making in all cases a tri-unity of the three colours called by artists homogeneous.

'With a view to throw such light upon the subject as my limited opportunities would permit, I went over the experiments by which Sir Isaac Newton established his theory, and the same results occurred: I could not separate any one colour of the solar spectrum into two. The imperceptible manner in which the colours were blended together upon the spectrum, however, and the circumstance of the colours which practical people call compound being always placed at the adjunct of the two of which they say it is composed, with my previous conviction, induced me to continue my experiments; and although I could not, by analysis, prove that there were only three colours, I succeeded in proving it to my own satisfaction, synthetically, in the following manner:—

'After having tried every colour in succession, and finding that none of them could be separated into two, I next made a hole in the first screen in the centre of the blue of the spectrum, and another in that of the red. I had thereby a spot of each of these colours upon a second screen. I then, by means of another prism, directed the blue spot to the same part of the second screen on which the red appeared, where they united, and produced a violet as pure and intense as that upon the spectrum. I did the same with the blue and yellow, and produced the prismatic green; as also with the red and yellow, and orange was the result. I tried, in the same manner, to mix a simple with what I thought a compound colour, but they did not unite; for no sooner was the red spot thrown upon the green than it disappeared.

'I tried the same experiment with two spectra, the one behind, and of course a little above the other, and passed a spot of each colour successively over the spectrum which was furthest from the window, and the same result occurred. It, therefore, appeared to me that these three colours had an affinity to one another that did not exist in the others, and that they could not be the same in every respect, except colour and refrangibility, as had hitherto been taught.

'These opinions, the result of my experiments, I published in 1828, as being a necessary part of a treatise of this nature; and I did so with great diffidence, well knowing that I was soaring far above my own element in making an attempt to throw light upon such a subject. I had, however, the gratification to learn that these facts were afterwards proved in a communication read to the Royal Society of Edinburgh by Sir David Brewster, on the 21st of March 1831, in which he also shewed that white light consists of the three primary colours—red, yellow, and blue; and that the other colours shewn by the prism are composed of these.

'The three homogeneous colours—yellow, red, and blue—have been proved by Field, in the most satisfactory manner, to be in numerical proportional power as follows—yellow, three; red, five; and blue, eight.

'When these three colours are reflected from any opaque body in these proportions, white is produced. They are then in an active state, but each is neutralised by the relative effect that the others have upon it. When they are absorbed in the same proportions, they are in a passive state, and black is the result. When transmitted through any transparent body, the effect is the same; but in the first case they are material or inherent, and in the second, impalpable or transient. Colour, therefore, depends entirely on the reflective or refractive power of bodies, as the transmission or reflection of sound does upon their vibratory powers.'

THE RAINBOW.

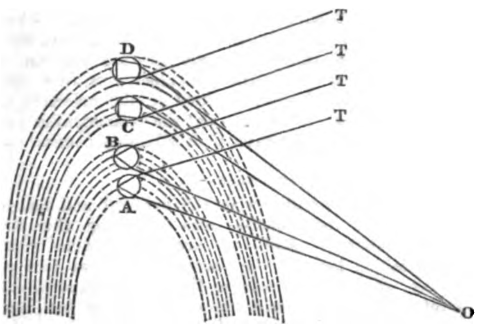
Every one is familiar with the brilliant and many-coloured arch occasionally seen spanning the sky during a shower. Rainbows are only visible when rain is falling between the spectator and that part of the sky which is opposite to the sun. The sun, the eye of the spectator, and the centre of the bow, are in a line; so that however far the sun is above the horizon, the centre of the bow must be as far below, and thus the bow is always less than a semicircle, except when the sun is just in the horizon. There are usually two bows or arches—the one inner or primary, the other outer or secondary; and within the primary rainbow, and in contact with it, and without the secondary one, there have been seen supernumerary bows.

The primary or inner rainbow, which is commonly seen alone, is part of a circle whose radius is 41°. It consists of seven differently coloured bows—namely, violet, which is the innermost, indigo, blue, green, yellow, orange, and red, which is the outermost. These colours have the same proportional breadth as the spaces in the prismatic spectrum. This bow is therefore only an infinite number of prismatic spectra, arranged in the circumference of a circle; and it would be easy, by a circular arrangement of prisms, or by covering up all the central part of a large lens, to produce a small arch of exactly the same colours. All that we require, therefore, to form a rainbow, is a great number of transparent bodies capable of forming a great number of prismatic spectra from the light of the sun.

Sir David Brewster thus explains the cause of the arc of the sky:—As the rainbow is never seen unless when rain is actually falling between the spectator and the sky opposite to the sun, we are led to believe that the transparent bodies required are drops of rain, which we know to be small spheres. If we look into a globe of glass or water held above the head, and opposite to the sun, we shall actually see a prismatic spectrum reflected from the further side of the globe. In this spectrum the violet rays will be innermost, and the spectrum vertical. If we hold the globe horizontal, on a level with the eye, so as to see the sun's light reflected in a horizontal plane, we shall see a horizontal spectrum, with the violet rays innermost. In like manner, if we hold a globe in a position intermediate between these two, so as to see the sun's light reflected in a plane inclined 45° to the horizon, we shall perceive a

spectrum inclined 45° to the horizon, with the violet innermost. Now, since in a shower of rain there are drops in all positions relative to the eye, the eye will receive spectra inclined at all angles to the horizon, so that, when combined, they will form the large circular spectrum which constitutes the rainbow.

To explain this more clearly—let AB be drops of rain exposed in the sun's rays, incident upon them in the direction TA, TB, out of the whole beam of light which falls upon the drop; those rays which pass through or near the axis of the drop will be refracted to a focus behind it; but those which fall on the upper side of the drop will be refracted, the red rays least, and the violet most, and will fall upon the back of the drop with such sufficient obliquity that many of them will be reflected, as shewn in the figure. These rays will be again refracted, and will meet the eye at O, which will perceive a spectrum or prismatic image of the sun, with the red space uppermost, and the violet undermost. If the sun, the eye, and the drops AB, are all in the same



vertical plane, the spectrum produced by AB will form the colours at the very summit of the bow, as in the figure. Let us now suppose a drop to be near the horizon, so that the eye, the drop, and the sun are in a plane inclined to the horizon, a ray of the sun's light will be reflected in the same manner as at AB, with this difference only, that the plane of reflection will be inclined to the horizon, and will form part of the bow distant from the summit. Hence it is manifest that the drops of rain immediately above the line joining the eye, and the upper part of the rainbow, and in the plane passing through the eye and the sun, will form the upper part of the bow; and the drops to the right and left hand of the observer, and without the line joining the eye and the lowest part of the bow, will form the lowest part of the bow on each hand. Not a single drop, therefore, between the eye and the space within the bow is concerned in its production; so that, if a shower were to fall regularly from a cloud, the rainbow would appear before a single drop of rain had reached the ground.

If we compute the inclination of the red ray and the violet ray to the incident rays TA, TB, we shall find it to be 42° 2′ for the red, and 40° 17′ for the violet, so that the breadth of the rainbow will be the difference of those numbers, or 1° 45′, or nearly three times and a half the sun's diameter. These results coincide so accurately with observation, as to leave no doubt that the primary rainbow is produced by two refractions and one intermediate reflection of the rays that fall on the upper sides of the drops of rain.

It is obvious that some of the rays will suffer a second reflection at the points where they are represented as quitting the drop; but these reflected rays will go up into the sky, and cannot possibly reach the eye at O. But though this is the case with rays that enter the upper side of the drop, as at AB, or the side furthest from the eye, yet those which enter it on the under side, or the side nearest the eye, may after two reflections reach the eye, as shewn in the drops DC, where the rays TT enter the drops below. The red and violet rays will be refracted in different directions, and after being twice reflected, will be finally refracted to the eye at O; the violet forming the upper part, and the red the under part of the spectrum. If we now compute the inclination of these rays to the incident rays TT, we shall find them to be 50° 58′ for the red ray, and 54° 10′ for the violet ray; the difference of which, or 3° 12′ will be the breadth of the bow, and the distance between the bows will be 8° 15′. Hence it is clear that a secondary bow will be formed without the primary bow, and with its colours reversed, in consequence of their being produced by two reflections and two refractions. The breadth of the secondary bow is nearly twice as great as that of the primary one, and its colours must be much fainter, because it consists of light that has suffered two reflections in place of one.

Many peculiar kinds of rainbows have been observed, such as lunar ones, in which, however, the colours are faint and barely perceptible. Supernumerary rainbows are sometimes seen. 'On the 5th of July 1828,' says Sir David Brewster, 'I observed three supernumerary bows within the primary bow, each consisting of green and red arches, and in contact with the violet arch of the primary bow. On the outside of the outer or secondary bow, I saw distinctly a red arch, and beyond it a very faint green one, constituting a supernumerary bow, analogous to those within the primary rainbow.'

Red rainbows, distorted rainbows, and inverted rainbows on the grass, have been observed. The latter are formed by the drops of rain suspended on the spiders' webs in the fields. It is only necessary to mention that the iris, so frequently seen overarching a cataract, is produced by the refraction of light in passing through the misty vapour generated by the falling water.

REFLECTION OF LIGHT.

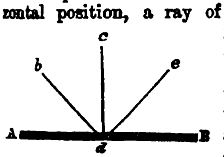
Light, as has been mentioned, is diffused around us by the refractive power of the atmosphere, and therefore objects are quite visible though the rays of the sun do not strike directly upon them; in plainer terms, the atmosphere may be compared to the thick piece of glass called a *bull's eye* fixed in the deck of a ship, by which rays of light are collected and dispersed into all corners of the apartment beneath. The atmosphere being thus a vehicle of light, it may be supposed that, if we were to ascend to a great height above the level of the earth, or beyond the sphere of the atmosphere, we should be almost in darkness, although we were in reality nearer the sun. There is reason to believe that such would be the case; for travellers who have ascended to the summit of Mont Blanc, or about 15,000 feet above the level of the sea, mention that at that height the sky appears to be of an exceedingly dark-blue colour, or almost black, and the light so faint that the stars are visible. We may understand from this, that the rays of the sun travel through immense regions of darkness before they reach our atmosphere, and are diffused into that universal soft light which we observe around us.

But besides being diffused by a pure atmospheric medium, light is greatly increased in brilliancy by *reflection*. If all the objects on the surface of our planet were to be black, which is a negation of all colour, the sun's light would be absorbed, or the objects would return no part of the rays which fell upon them; and we should, even while the sun shone, possess much less light than we now enjoy. Nature has avoided this calamity, and by producing all varieties of colours in objects, the sun's rays which fall upon them are less or more reflected, or sent back into the general mass of light. We now, then, understand that every object we see reflects rays of light, and that these rays travel from the object to our eye, as soon as we bend our vision upon it: inasmuch, however, as a thousand or more individuals may see the same object at the same instant

of time, it is evident that the rays emanate at all points, and fall upon eyes at every variety of angle.

If the object be clear or polished in its surface, it will possess the power of representing the image of objects whose rays fall on it. Thus the surface of a smooth lake will represent the image of the sky above, or the neighbouring hills, or of any object floating on its surface. This natural property in clear surfaces has suggested the formation of mirrors or looking-glasses. A mirror, or *speculum*, as it is scientifically called, is any instrument of a regular form, employed for the purpose of reflecting light or forming images of objects. Mirrors usually consist of metal or glass, having a highly polished surface. Those which are constructed of glass are coated upon the back with quicksilver, or rather with tinfoil mixed with a little mercury, for the purpose of reflecting more light: were this not the case, so little light would be thrown back, on account of glass transmitting it to a considerable extent, that a very indistinct image would be formed. The word speculum is generally confined to metallic mirrors, and they are either plane, concave, or convex. The plane ones are perfectly flat, like a looking-glass; and a common watch-glass conveys a very good idea of the other two species of mirrors. Coat the hollow surface with mercury, and place it before a candle—it forms a convex mirror; coat it upon the other side, and employ it as before—it becomes a concave mirror.

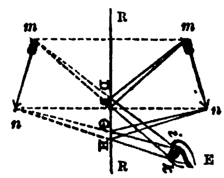
If a plane mirror AB be placed exactly in a horizontal position, a ray of light *c* darting downwards in an exactly perpendicular direction, and striking it at *d*, will be thrown back in the exact path which it traversed in its descent, without any deviation. If, however, it descends in an oblique manner, as is shewn at *e*—a point midway between the perpendicular *c* and the horizontal AB—it will not return, as in the former instance, to the place whence it came, but will be reflected from the mirror at an angle exactly equal to that at which it descended upon it. The ray *ed* is called the *incident* ray, and *db* the *reflected* ray. In the figure, *edc* is called the *angle of incidence*, and *bdc* the *angle of reflection;* and they are, as we have observed, exactly equal to each other. The one, then, can in all cases be inferred from the other. This holds true whatever shape the mirror may be of—plane, concave, or convex—and whatever number of rays may fall upon it.



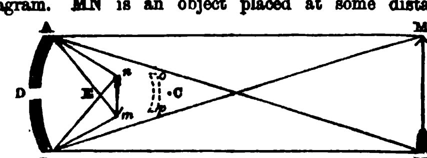
Let us apply the principle here mentioned to the simple phenomenon of seeing ourselves in a plane looking-glass. When we stand directly in front of a mirror, we see our image represented in it; and as we move, so does the image appear to move also, but with a peculiarity in its motion: if, for example, we walk towards the mirror, the image is seen to approach in a similar manner, but the approach is with double the velocity, because the two motions are equal and contrary. Suppose, however, while we stand at the glass, another person walks up behind us, his image will appear to us to move at the same rate as he walks, though to him the velocity will seem double, because, with regard to us, there will be but one motion, and with regard to him there will be two equal and contrary motions.

In the case of standing directly in front of the mirror, the image is necessarily before us, for the rays proceeding from our eye to the mirror are sent back from the surface without any angle of incidence. The case is otherwise when we stand so far at a side that we cannot see ourselves in the glass, though we can see the image of another person equally far off on the opposite side. Two persons so situated will see each other though they cannot see themselves, because the line of rays from the first person striking on the glass form an angle of reflection, and dart off in the direction of the second person, while the rays from the second person are similarly reflected towards the first. Such is a practical exemplification of the angle of reflection in mirrors.

The principle of reflection may be more minutely explained as follows:—We suppose RR to be the surface of a plane mirror, the arrow MN any object placed in front of it, and E the eye of an observer placed at *ik*. Of the rays which shoot in a rectilinear direction from the points MN of the object, and are reflected from the mirror, those which enter the eye are few in number, and must be reflected from portions DF and GH of the mirror, so situated with reference to the eye and the object, that the angles of incidence of the rays which fall on these portions must be equal to the angles of reflection of those which enter the eye between *i* and *k*. For instance, the ray MD is reflected in the direction D*i*, and the ray MF in the direction F*k*. In the same manner, the rays NG and NH will be reflected severally in the directions G*i* and H*k*. If the rays *i*D and *k*F be continued backwards, they will meet at a point *m*, whence they will appear to have come to the eye. For the same reason, the rays G*i* and H*k*, if continued in the same manner, will seem to meet at the point *n* as their focus, and *mn* will be the virtual image of the object MN. It is called *virtual*, because it is not formed by the actual union of rays in a focus, and cannot be received upon paper. The virtual image *mn* is as far behind the mirror as the object MN is before it; consequently, if we join *mn*, it will be of the same dimensions as MN, and have the same position behind the mirror as the object has before it. If we join the points M*m* and N*n* the lines M*m* and N*n* will be perpendicular to the mirror RR, and consequently parallel. In every position of the eye the image is seen in the same spot; its absolute size is always the same, and its apparent size is also the same when seen at equal distances from the eye. If the object MN is an individual surveying himself in the mirror, he will see his perfect image as if at *mn*.



The manner in which rays are reflected from a concave mirror, next deserves our attention. It will have been frequently observed by the reader, that when he looked at himself in the hollow of a polished metal spoon, his face and bust appeared to be inverted, or upside down. We explain this by referring to the accompanying diagram. MN is an object placed at some distance



from a concave mirror AB, whose centre is C, and whose principal focus is E. The rays from M fall diverging upon the mirror, and are reflected to a focus at *m* (a little without the principal focus), where they form an image of the extremity M. In the same way, a representation of the extremity N will be painted at *n*, so that a complete but inverted image of NM will thus be formed; and it is evident that it will be very bright, though small, because a great number of rays are concentrated, and concur in forming each point of the image. The size of the image thus formed corresponds to the distance of the object from the mirror. If the latter be large, and the former very bright, a series of beautiful experiments may be made by varying the distance of the object, and observing the variations in the size and place of the image. As the object recedes from the mirror, the picture approaches E, and gradually decreases in size.

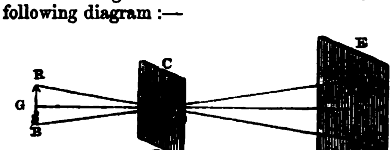
If we consider *mn* as a small object, a magnified

representation of it will be formed at MN, which, when viewed by a convex lens, such as will be afterwards described, constitutes a *reflecting microscope.* If we place a small concave mirror *op* behind it, so as to enlarge the image, and reflect the rays through an opening D in the large mirror AB, then this second image may be magnified still more by means of a lens, in which case it constitutes a Gregorian reflecting telescope. If instead of a concave we employ a convex mirror *op*, and place it between E and *nm*, so as to reflect the rays which would otherwise have met at *nm*, then an enlarged image would in this case also be painted at D, where it can be magnified as in the former instance.

An image formed by a concave mirror is always highly magnified when the object is near the focus; but as it passes that point, and approaches the mirror, the image gradually decreases in size, and becomes equal to the object when the latter touches the mirror. Indeed, when the object is placed between the principal focus and the mirror, the image is a virtual one apparently formed behind the mirror, or would be so formed behind it if the substance of the mirror permitted. Concave mirrors, from their property of converging rays into a focus, may be used as burning-glasses; practically, mirrors of this shape are used to gather the rays from lamps, and reflect them, with increased brilliancy, into the darkness. The lamps of coaches, light-houses, &c., are fitted up with these reflectors.

With respect to convex mirrors, they always form images of a diminished size, because the rays which form them become convergent in their passage to the eye of the spectator; in other words, the rays from the object proceed to a virtual or imaginary focus behind the mirror, and thence the image, in a miniature form, seems to be reflected to the eye. In this, as in all cases of reflection from concave mirrors, the size of the image represented is exactly what it might be expected to be if we could see through the glass, and observe the dimensions at the virtual focus.

It is perhaps not generally known that images may be formed upon a piece of paper, by placing a small hole between the object and the paper, and excluding all extraneous light. This will be best understood by the following diagram:—

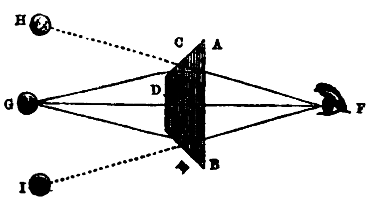


Let CD be a window-shutter having a small aperture A, and EF a piece of paper placed in a dark chamber. Then, if an illuminated object RGB is placed on the outside of the shutter, we shall observe an inverted image of this object painted on the paper at *rgb*. In order to understand how this takes place, let us suppose the object RGB to have three distinct colours—*red* at R, *green* at G, and *blue* at B; then it is plain that the *red* light from R will pass in straight lines through the aperture A, and fall upon the paper EF at *r*. In like manner, the *green* from G, and the *blue* light from B, will severally fall upon the paper at *g* and *b*, and an inverted image *rgb* of the object RGB will be painted upon it. Every coloured point in the object RGB having a coloured point corresponding to it, and opposite to it, on the paper EF the image *bgr* will be an accurate picture of the object RGB, provided the aperture A is very small. If it be increased in size, indistinctness in the image will ensue; for with a large aperture, two adjacent points of the object will throw their light on the same point of the paper, and thus create confusion in the picture. It is perfectly clear that if the paper EF be moved to a further distance from the hole A, the size of the image will be increased; and if it be brought nearer to it, it will be diminished.

LENSES.

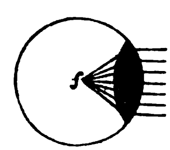
Lenses, as already mentioned, are of different forms, and consequently possess different refractive powers. A lens may be composed of any transparent substance —as glass, diamond, a globule of water, &c.; in the arts, a lens is made of glass, as pure and colourless as possible. The design in forming lenses is to procure a medium through which the rays of light from any object may pass, and converge to a corresponding point beyond. The manner in which the rays proceed through the glass, and then centre in a focal point, will depend on the form of the lens, its capacity for refraction, and the distance of the object.

If we take a piece of glass, flat on one side, and cut into different faces on the other, and then look through it from the flat side at any object—for instance, a pea, we shall see as many peas as there are faces receiving the rays from the single pea. We may exemplify this principle of multiplication by the following figure, in which AB is a lens flat on one side, and cut into three faces on the other CDE. F is the eye of the spectator, and G the pea to be looked at. The eye receives a pencil of rays direct through the lens at D, and sees the object without refraction. A pencil also proceeds from

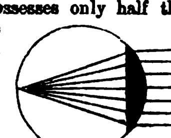


G to the face C, and another pencil to the face E, and in both cases the rays are bent and refracted to the eye. This eye, however, does not recognise the path of either of these oblique rays, but perceives the image of a pea at H and at I; and thus three peas seem to be seen in place of only one.

In smoothly ground lenses, in which there are no distinct faces to multiply the images of an object, the rays bend, as we have said, so as to meet in a corresponding point beyond them. A lens may consist of a perfect globe of glass, or globe filled with pure water, in which case the refractive power will be considerable; a double convex lens, which is the more common kind, may be viewed as a portion cut out of the side of a sphere, as seen in the annexed fig.

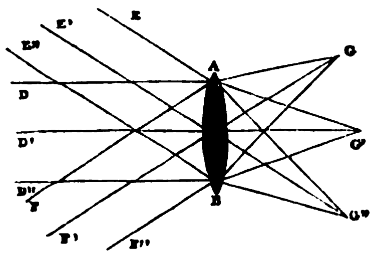


Here, as in all such cases of convexity, the focus of the parallel rays passing through the lens is at *f*, which is the centre of the sphere of which the further or anterior side is a portion or a point at half the diameter, or *radius*, of the sphere from it. Should we take a plano-convex lens, the focal point would be considerably different. In the next figure we have an example of this kind of lens, which evidently possesses only half the refractive power of the double convex glass.



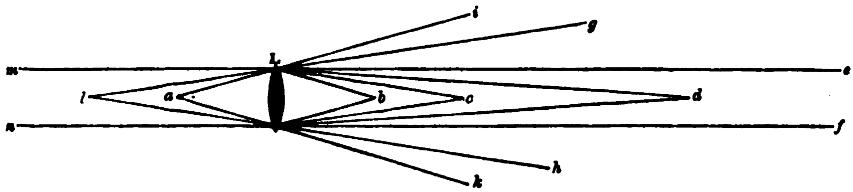
Here the parallel rays, falling on the convex side of the lens, are seen to converge at the distance of the whole diameter of the sphere. Thus the focal point at which the rays of light fall is always regulated by the degree of curvature of the lens. We shall illustrate this by various diagrams, to which we ask the reader's careful attention, for the subject is somewhat difficult, and cannot be comprehended by a superficial glance.

We take a double convex lens represented by AB, the axis of which is the line G'CD'. The ray D'G', being straight through the centre, suffers no refraction;



but the rays DA and D"B are refracted so as to meet at the focal point G'. We now observe that the parallel rays EA, E'C, and E"B, and also FA, F'C, and F"B, falling obliquely on the lens, will in a similar manner be refracted, and have their foci at G and G", at the same distance from the lens. Those lines which pass through the centre—as E'CG" and F'CG—do not alter their direction, not being refracted. Thus, in whatever way parallel rays pass through a lens, we have a focal point beyond it, be it straight forward or in an oblique direction.

The distance at which the rays meet beyond the lens is exemplified in the next diagram, given by Dr Arnott in his treatise on Physics, and whose definition of the focal point we beg leave to offer:—'Rays falling from *a* on a comparatively flat or weak lens at L, might meet only at *d*, or even further off; while with a stronger or more convex lens, they might meet at *c* or at *b*. A lens weaker still might only destroy the divergence of the rays, without being able to give them any convergence, or to bend them enough to bring them to a point at all, and then they would proceed all parallel to each other, as seen at *e* and *f;* and if the lens were yet weaker, it might only destroy a part of the divergence, causing the rays from *a* to go to *g* and *h*, after passing through, instead of to, *i* and *k*, in their original direction.



'In an analogous manner, light coming to the lens in the contrary direction from *bcd*, &c., might, according to the strength of the lens, be all made to come to a focus at *a* or at *l*, or in some more distant point; or the rays might become parallel, as *m* and *n*, and therefore never come to a focus, or they might remain divergent.

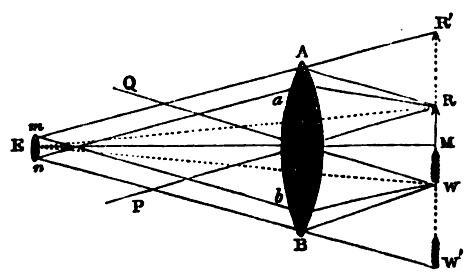
'It may be observed in the above figure that the further an object is from the lens, the less divergent are the rays darting from it towards the lens, or the more nearly do they approach to being parallel. If the distance of the radiant point be very great, they really are so nearly parallel that a very nice test is required to detect the non-accordance. Rays, for instance, coming to the earth from the sun do not diverge the millionth of an inch in a thousand miles. Hence, when we wish to make experiments with parallel rays, we take those of the sun.

'Any two points so situated on the opposite sides of a lens, as that when either becomes the radiant point of light, the other is the focus of such light, are called *conjugate foci*. An object and its image formed by a lens must always be in *conjugate foci;* and when the one is nearer the lens, the other will be in a certain proportion more distant.

'What is called the *principal* focus of a lens, and by the distance of which from the glass we compare or classify lenses among themselves, is the point at which the sun's rays—that is, parallel rays—are made to meet; and thus, by holding the glass in the sun, and noting at what distance behind it the little luminous spot or image of the sun is formed, we can at once ascertain the focus of a glass as at *a* for the rays *e* and *f*.'

If a convex lens, with a focal length less than the distance of distinct vision, is placed between the eye and an object situated in the focus of the lens, the rays of each pencil proceeding from any point in the object will emerge parallel, and an image of it will be seen distinct and *magnified*. 'The size of the image will be to that of the object as the distance of distinct vision to the focal length of the lens.'

The cause of the parallelism of the emergent rays and of the enlargement of the image may be thus explained: Let E be the eye, and *mn* the diameter of its pupil, and RW a small object placed at the least distance of distinct vision. When the lens AB is placed so that RW is in its focus, the conical pencil of rays proceeding from any point R, having the first surface of the lens for its base, will, after passing through the lens, emerge in a cylindrical pencil parallel to the central ray RCP, or the axis of the incident conical pencil; but only a small portion of the refracted pencil—namely, the small pencil *Amna*—will fall on the pupil and enter the eye, and form on the retina an image of the point R. Now this point will be seen in the direction of the point *mA*, or at R'; in like manner, the other extremity W will be seen at W', and the points intermediate to R and W will have

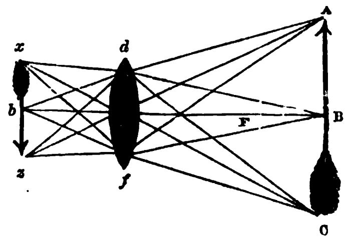


images intermediate between R' and W'. Thus the whole image will exceed the object in the proportion of R W' to RW; but these lines are to one another as EM to CM, or as the distance of distinct vision to the focal length of the lens.

The visual angle REW would be to the angle R'EW' nearly as RW to R'W'; so that the visual angle is enlarged in the ratio of the distance of distinct vision to the focal length of the lens. A convex lens, from the property it possesses of enlarging the apparent size of objects, is called a *magnifying-glass* or a *single microscope*.

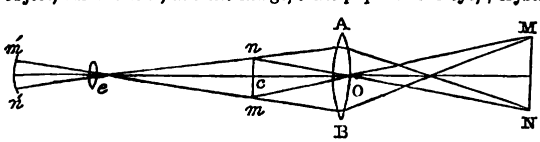
An object may be magnified on a different principle, by using a lens whose focal length exceeds the distance of distinct vision. It is evident from the preceding article, that when the focal length is equal to this distance, the image is of the same size as the object. Let now the focal length exceed this distance, and let an object AC be placed beyond F, the principal focus; it

will form an image xbz, which may be seen as if it were a real object, by an eye placed at the distance of distinct



vision; for rays proceed from points in the image just as if it were a real object, only not in all directions. The image of the point A will be at z, of B at b, and of C at x. These conjugate foci are computed by the rules formerly laid down. The image is necessarily *inverted*. If the object AC is very distant compared with the focal length of the lens, then the distance of the image from the lens will be very nearly its focal length, and the magnifying power will be determined thus:—'As the least distance of distinct vision is to the focal length of the lens, so is the apparent size of the object seen by the naked eye to its apparent size seen by means of the lens.'

The proof of this theorem is as follows:—MN is the object, AB the lens, mn the image, e the pupil of the eye,



and $m'n'$ the image on the retina of the eye. The object MN being distant, the image mn will be nearly in the principal focus of the lens AB, so that Oc is its focal length. The apparent magnitude of the object, if seen by an eye placed at O, would be measured by the angle MON; and as Oe, the sum of the distance of distinct vision ec and cO, is small compared with OM, the distance of the object, the angle MON may be considered as the visual angle of the object seen by the unaided eye. Now, the angle nem formed at e by the crossing rays ne, me, is the visual angle of the image mn; hence the apparent size of the object compared with that of its image is as those visual angles—that is, as the angle MON or mOn to men. But these angles are as their halves—namely, the angles cOn, cen, which, from the properties of a triangle, are as the opposite sides ne and nO, or very nearly as ce and cO; but ce is the distance of distinct vision, and cO the focal length of the lens; hence the theorem is as stated above.

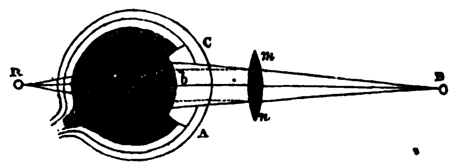
Example.—Let ce be 8 inches, and cO 32 inches; then the apparent size is increased in the ratio of 8 to 32, or 1 to 4; or the magnifying power is 4.

THE EYE—VISION.

Having, in our ACCOUNT OF THE HUMAN BODY, described the anatomical construction of the eye, we shall here confine ourselves to the actual process of vision. As mentioned in the article referred to, the eye, in front, consists of the *iris*, or variously coloured ring, which has the property of contracting or expanding to regulate the admission of light through the little dark spot in the centre called the *pupil*. Immediately behind the iris and pupil, there is a transparent substance resembling in shape a double convex glass, which is thence called the *crystalline lens*. The use of this lens is to collect and refract the rays of light, so that they may converge to a point beyond; in other words, cause them to fall on the back part of the eye, called the *retina*. Such are the main instruments of vision; and the sense of seeing is produced by certain nerves which convey intelligence of the image on the retina to the brain. If these nerves be injured, the image will still be pictured on the retina, but the mind will possess no power of recognising their presence.

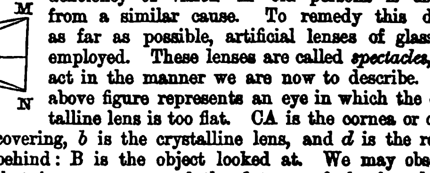
It will be understood from these explanations that the main instrument of vision is the crystalline lens, which collects the rays, and brings them to a focus on the retina. If the lens be perfectly transparent, and of the proper convexity, the light is enabled to act with due effect on the retina, and the representation of the object looked at will be correctly pictured to the mind. But if the transparent coating of the eye be dull, or the lens be either too flat or too convex, every object will appear dim.

Two kinds of defective vision are more common than any other, and they are known by the name of



long-sightedness and *short-sightedness*. Long-sightedness, or the power of seeing objects best at a considerable distance, is caused by too great a flatness in the crystalline lens and outer coating of the eye; and the deficiency of vision in old persons is usually from a similar cause. To remedy this defect as far as possible, artificial lenses of glass are employed. These lenses are called *spectacles*, and act in the manner we are now to describe. The above figure represents an eye in which the crystalline lens is too flat. CA is the cornea or outer covering, b is the crystalline lens, and d is the retina behind: B is the object looked at. We may observe, that in consequence of the flatness of the lens b, the rays proceeding from the object are not sufficiently refracted, but proceed to a focus as far back as R; in other words, the focus would be at R, if the retina would permit; but as the retina is in the way, the rays, from not being focalised upon it, cause imperfection in the vision. To remedy this, we interpose an artificial convex lens, or glass of a pair of spectacles mn, and by its aid the rays, represented by dotted lines in the figure, are brought to a focus on the retina at d. Thus, by selecting spectacles of a proper focalising power in relation to the eyes, one kind of imperfect vision is very happily remedied.

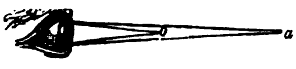
Short-sightedness arises from a cause the reverse of that just alluded to, being produced by too great a degree of convexity in the crystalline lens and cornea. In this case the rays come to a focus too soon within the eye, and do not reach the retina, unless the object



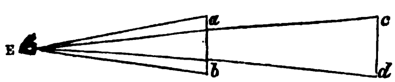
is brought quite close to the organs of vision. We here offer a representation of this condition. In consequence of the projecting globularity of the cornea CA, and the too great refracting power of the crystalline lens, the rays from the object B fall short of the retina at R. To remedy this, we interpose a double concave lens LL, by which the rays are rendered more divergent before they reach the eye, and are brought to a focus, where they should be, on the retina.

We have said above, that in short-sighted persons the

rays do not reach the retina unless the object is held close to the eyes. The effect produced by this is similar to that of employing concave spectacles; because the nearer we hold an object to our sight, the angle of the rays from it is the wider; the rays are more expanded before they enter the eye—that is, more divergent. Thus the extreme rays from a point to the pupil of the eye make a greater angle at *o*, than those from a point of a more distant object make at *a*; that is, the rays from *o* are more divergent on entering the eye than the rays from *a*, and thus nearness of an object is equivalent to seeing it at a greater distance through a concave lens. So when the object *a* is further distant than *o*, the rays from *a* have a less divergence, which is equivalent to viewing it at a nearer distance with a convex lens. These remarks, however, refer merely to the distinctness of the vision, and not to the apparent size of the object.



The apparent magnitude of the same object when viewed at different distances, depends on the size of what is called the *visual angle*—that is, the angle formed at the eye by the rays from the extremities of the object. We may exemplify this as follows:—



An eye, E, is looking at an object *ab*, and another object *cd*, of the same size, at double the distance. It is evident that the rays from *ab* are more expanded, or cause a larger angle on the eye, than the rays from *cd*. Various familiar phenomena are explained from the law of the visual angle under which an object is seen; the apparent size being less always in proportion as the distance of an object is greater. Hence the principles of perspective in drawing, by which objects are made to appear at a great distance in the background of a picture, although in reality they are as far forward as the objects in front.—(See DRAWING AND PERSPECTIVE.)

Another important circumstance connected with vision requires to be noticed. In consequence of the refractive power of the crystalline lens, the rays from an object fall upon the retina in such a manner that the image is there pictured upside down; and this inversion of the real appearance of things requires to be corrected by an act of the mind under the influence of experience. We beg leave to offer Dr Arnott's explanations on this somewhat puzzling point:—'Because the images formed on the retina are always inverted as respects the true position of the objects producing them—just as happens in a simple camera obscura—persons have wondered that things should appear upright, or in their true situations. The explanation is not difficult. It is known that a man with a wry neck judges as correctly of the position of the objects around him as any other person, never deeming them to be inclined or crooked, because their images are inclined in relation to the natural perpendicular of his retina; and that a bedridden person, obliged to keep his head upon his pillow, soon acquires the faculty of the person with wry neck; and that boys who at play bend themselves down to look backwards through their legs, although a little puzzled at first, because the usual position of the images on the retina is reversed, soon see as well in that way as in any other. It appears, therefore, that while the mind studies the form, colour, &c., of external objects in their images projected on the retina, it judges of their position, not by the accidental position of the images on the retina, but by the direction in which the light comes from the object towards the eye, no more deeming an object to be placed low because its image is low in the eye, than a man in a room into which a sunbeam enters by a hole in the window-shutter deems the sun low because its image is on the floor. A candle carried past a keyhole throws its light on the opposite wall, so as to cause the luminous spot there to move in a direction the opposite of that in which the candle is carried; but a child is very young indeed who has not learned to judge at once of the true motion of the candle by the contrary apparent motion of the image. A boatman, who, being accustomed to his oar, can direct its point against any object with great certainty, has long ceased to reflect, that to move the point of the oar in some one direction, his hand must move in the contrary direction. Now the seeing things upright, by images which are inverted, is a phenomenon akin to those here reviewed.'

The same able writer on physics thus explains another peculiarity in visual arrangements—namely, why, from having two eyes, the object does not appear to us to be double: 'In answer to this, we shall only state the simple facts of the case. As in two chess-boards there are corresponding squares, so in the two eyes there must be corresponding points, and when on those points a similar impression is made at the same time, the sensation or vision is single; but if the impression be made on points which do not correspond, owing to some disturbance of the natural position of the eyes, the vision becomes double. Healthy eyes are so wonderfully associated, that from earliest infancy they constantly move in perfect unison. By slightly pressing a finger on the ball of either eye, so as to prevent its following the motion of the other, there is immediately produced the double vision; and tumours about the eye often have the same effect. Persons who squint have always double vision, but they acquire the power of attending to the sensation in one eye at a time. Animals which have the eyes placed on opposite sides of the head, so that the two can never be directed to the same point, must possess this faculty in a more remarkable degree.

'The corresponding points in the two eyes are equidistant, and in similar directions from the centres of the retinæ, which centres are called the *points of distinct vision*, and at them the imaginary lines named the axes of the eyes terminate; but it is worthy of remark that these points, in being both to the right or both to the left of the centres, must be one of them on the inside of the centre, as regards the nose, and the other on the outside—that is to say, a point of the left eye between the centre and nose has its corresponding point in the right eye between the centre and the cheek—and from this fact arise consequences meriting attention. When the two eyes are directed to any object, their axes meet at it, and the centres of the two retinæ are opposite to it, and all the other points of the eyes have perfect mutual correspondence as regards that object, giving the sensation of single vision; but the images formed at the same time, of an object nearer to or further from the eye than the first supposed, cannot fall on *corresponding* points; for an object nearer than where the axes meet, would have both its images on the outsides of the centres, and an object more distant would have both its images on the insides of the centres—and in either case the vision would be double. Thus if a person hold up one thumb before his nose, and the other in the same direction, but further off, by then looking at the nearest, the more distant will appear double, and by looking at the more distant, the nearest will appear double. The reason for applying the term "point of distinct vision" to the centre of the retina, is felt at once by looking at a printed page, and observing that only the one letter to which the axis of the eye is directed is distinctly seen; and consequently that, although the whole page be depicted on the retina at once, the eye, in reading, has to direct its centre successively to every part.'

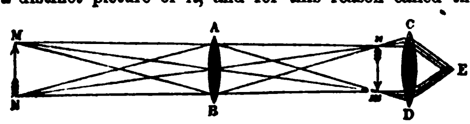
The retina of the eye possesses such exquisite sensibility, that it retains the impression of the image of any bright object presented to it for the space of the eighth of a second after the object has been withdrawn, or after the eye has been shut. Thus the burning end of a

rapidly whirled stick will appear to form hoops of fire; and a fiery meteor or sky-rocket shooting rapidly through the air, will appear as a long line of light.

The optical portion of the eye reveals nothing but surfaces variously extended and coloured. It requires experience to judge of the distance, size, solid shape, and other qualities of the objects painted on the retina. The greater part of what we think we see, we only *infer*. It has been shewn by Professor Wheatstone that the vivid conception we have of solid forms arises from the conjoint action of the two eyes upon one and the same body. Since the eyes are some distance apart from each other, if they are directed upon any object they will see different faces of it—the right eye will see one aspect or surface, and the left eye will see a different aspect, as if viewed from a point to the left. Now, the coalition of the two aspects, or the embrace of the object between the two glances, has the effect of giving a distinct and strong impression of solidity—an effect which has been imitated by Professor Wheatstone by means of an instrument called the *stereoscope*, where two different views or drawings of an object, taken from points a little apart, are made by mirrors to be viewed by the two eyes separately. At the moment the two images coincide in the view, or cover one another, a solid body seems instantaneously to start out, and the illusion of the perspective is complete.

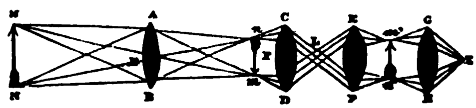
OPTICAL INSTRUMENTS.

Telescopes.— Telescopes, sometimes called spying-glasses, are instruments in the form of tubes, fitted up with lenses of different kinds and powers, and used for examining distant objects. The word telescope is derived from two Greek words signifying *afar off*, and *to see*. A telescope, in its simplest construction, contains two lenses—one is used to create a picture of the object looked at, and therefore called the *object-glass;* the second to magnify that picture, or, more properly, to enable the eye to come very close to it, and yet have a distinct picture of it, and for this reason called the



eye-glass. Two convex lenses properly adjusted, as above, constitute the simplest form of the telescope. Let the arrow MN stand for any outward object, and let its rays fall upon a convex lens AB, which is seen edgeways in the figure. The rays will be all bent, so that, at a certain distance on the other side of the lens, a new representation of the arrow *nm* will be made. The rays from the point of the arrow at M will be so acted on at the two surfaces of the lens, that they will all come together again, and make, as it were, an arrow-point at *m*. The rays from the feather at N will fall into their places at *n*, in a new arrow-head; and so on throughout, the whole being inverted. A second lens CD is used, not to form a second picture (as it would do if distance were allowed it), but to enable the eye at E to look closer at *nm* than it could otherwise do. What the eye sees, therefore, by the two lenses, is a near picture of the original arrow turned upside down. This picture is nearer and larger to the sight in proportion to the roundness of the magnifying lens. Suppose the image *nm* is six inches from the picturing or *object* lens, then if the eye look at it at a distance of six inches, the picture will have the same apparent size as the original, and nothing will be gained. But if the second lens, or *eye-piece*, enables the eye to come within one inch of the picture, and yet see it without confusion, it will be thirty-six times as large to appearance as the original—six times each way. In fact, the view is now improved as much as if a six-mile object were brought within one mile. Now, the greater the distance of the picture from the object-lens which forms it, the greater its focal distance; and the nearer that the eye can be brought to the picture by the eye-lens, the larger the appearance will be, or the greater will be the magnifying power of the telescope. Two such lenses shut up in a tube make what is called the *astronomical telescope*. In looking at the heavens, the inversion of the picture causes no inconvenience.

For land-objects, which must appear erect, a telescope is formed with additional lenses, which make a second picture, as in next fig. The lens AB makes the first picture, and the two lenses CD and EF cross the rays



again, and make a second picture, which is upright. This is viewed by the eye-piece GH. To increase the power of these telescopes, the object-glass AB is made with a very long focus, or so as to form its picture as far off from itself as possible. This requires its shape to be very much flattened, and still to preserve a perfect roundness—a matter difficult of execution. All lenses are more or less imperfect; that is, the picture they form is liable to be somewhat confused, which takes off from the advantage of the instrument. The greatest evil is one that cannot be cured by a single lens—that is, the fringing or colouring of the picture. But this action has been done away with by using a double lens, or two lenses of different kinds of glass joined together. The difference in the quality of the glasses to produce colour is so managed that they neutralise one another; and a picture free from coloured and indistinct edges is produced. This compound lens is called *achromatic*, or wanting in colour. With these lenses very perfect telescopes are made of two, three, six, or ten feet in length, and with eye-pieces of half or quarter of an inch, and under, of focal distance. A three-feet telescope—that is, a telescope where the picture is made thirty-six inches from the object-glass, and an eye-piece that lets the picture come within half an inch of the eye (a half-inch eye-piece)—would magnify seventy-two times each way, and have the same effect as if the distance of the original were divided by seventy-two. This and other instruments in which refracting lenses are employed, are called *refracting telescopes*, and they magnify or bring near in proportion as the focal distance of the object-glass is greater than the focal distance of the eye-glass.

Refracting telescopes require to be of considerable length where much power is required, and on that account reflecting telescopes are for many purposes preferred. The *reflecting telescope* was invented by Sir Isaac Newton, but has been much improved since his time. A view of the improved instrument is given beneath. The peculiarity of this instrument is, that the

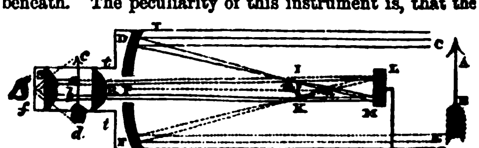


image of the object is reflected from a concave mirror within the tube, and this image is again reflected from a small mirror to the eye. Referring to the figure, T is the tube, and AB the object to be represented. At the end opposite from the object, there is a small tube *tt*. At the main end of the wide tube, there is a concave mirror DF, with a hole in the middle at P. The principal focus of this mirror is at IK; here the image *m* is inverted, and the rays, crossing each other at *n*, go on to the small reflector LM. From this they are reflected in parallel lines through the hole P. At P they enter the plano-convex lens R, which causes them to converge at *ab*; but here the

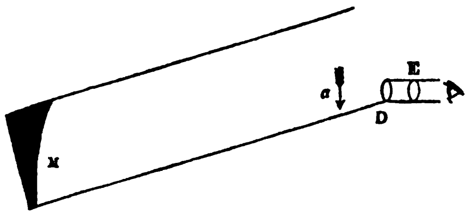
image requires to be magnified, which is done by means of the plano-convex lens S; in other words, the object is seen under the angle *cfd*. In order to accommodate focal distances, the small mirror L can be removed to a greater distance or brought nearer, by the rods and screws communicating from S.

Sir William Herschel got over the difficulty of placing the observer out between the object and the mirror, by a simpler arrangement. He gave the mirror M at the bottom of the tube a slight slope, so that



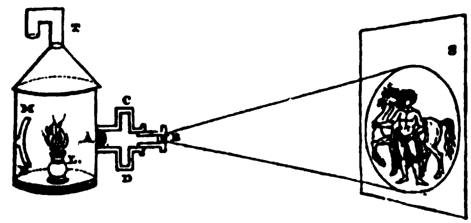
it sends its image to *a*, at the edge of the tube's mouth, where it is viewed by the eye-piece E without bringing the observer's head between the thing viewed and the mirror. On this principle he constructed telescopes of gigantic dimensions and power. His greatest was forty feet long, and the mirror four feet wide. The use of a large mirror is to take in more light, which is apt to fail in using high magnifying powers. With an eye-piece of an inch focus, the power of such a telescope would be 480 each way, which would magnify a surface nearly a quarter of a million of times. The moon would be seen by such a power, as if she were brought within 500 miles of us, her real distance being 240,000.

But Lord Rosse has surpassed Herschel in the construction of reflecting telescopes. The chief difficulty in making monster telescopes (apart from the stupendous machinery for supporting and moving them) is the forming of the mirror or speculum, which is of metal, and requires to have a surface of high polish and reflecting power, and at the same time to be ground into a perfectly spherical or rather parabolic form: the mixing of the ingredients to make a good shining metal, and the casting of an immense mass, like a millstone, of an even hardness throughout; and, lastly, the grinding, shaping, and polishing of the surface, make a series of operations of the utmost difficulty. After succeeding in the manufacture of the speculum, Lord Rosse has gone on to construct two telescopes of immense power—the one twenty-six feet long; the other, 'the monster telescope,' fifty-six feet, the focal length of the mirror being fifty-two feet. The fifty-six feet tube is seven feet wide; the mirror at the bottom is six feet wide, with a glittering polish all over the surface, and weighs three tons. This telescope is said to bear a power magnifying of more than 5000 diameters.

Microscope is a term compounded of two Greek words, signifying *small*, and *to see*, and denotes that instrument employed to examine minute objects. Those microscopes of greatest power, and termed compound, approach to the telescope in their form. The difference lies in this, that whilst in the telescope the object-glass forms the image of a distant object just as much smaller than itself as the distance of the image from the glass is less—in the microscope, conversely, a small object, placed near the focus of the object-glass, produces a more distant image, as much larger than itself as the image is more distant. In both cases, an appropriate eye-glass is employed. The object-glass of a microscope is in general very small, that of a telescope large. An object-glass of a microscope having one-eighth of an inch of focal distance, and so placed as that the image of the object is formed at six inches, the image will be of a diameter forty-eight times as great as the object; and when viewed through an eye-glass of half an inch focus, it will appear magnified twelve times more, or will appear 30,000 times larger than the object. A single or one-lens microscope magnifies chiefly by allowing the eye to see the object nearer than it could do without the glass.

A *Camera Obscura*, or *Dark Chamber*, is formed by placing a convex lens in an aperture made in the window-shutter of a darkened room. A glass of proper size and focal distance is chosen, and a screen, or the wall of the chamber, is properly prepared to receive the light; and by this means there is painted on it an accurate picture of all the objects seen from the window, everything bearing an exact resemblance to the reality.

The Magic Lantern.—When a small object is placed close to a lens, and the image reflected upon the wall of a dark chamber, at, say, one hundred times further from the lens than the object is, there will be a greatly magnified representation of the object. It will only be seen, however, under ordinary illumination; and it is therefore necessary to have a very strong light, concentrated by a suitable mirror or glass, and directed upon the object. When artificial light is employed, as of a lamp, the instrument then becomes a magic lantern. It consists of an argand burner placed in a dark lantern, on one side of which is a concave mirror, the vertex being opposite to the centre of the flame, which is placed in its focus. The lantern is made of tin japanned; and to



carry off the smoke from the flame, it is provided with a tube T at the top. L is the light, and MN a concave mirror to give strength to the light, and send the rays through the tube AB in front. At A in this tube is a hemispherical illuminating lens, and there is a convex lens at B. In the middle of the tube there is a wide part CD, open at the sides, for the reception of *slides*. These slides are slips of glass on which pictures are painted; and the principle of the apparatus consists in forming a representation of the picture, in a magnified size, on a distant white wall or screen S. The slide being placed in one of the conjugate foci of the lens B, the image is consequently enlarged. By bringing the lantern nearer the screen, we diminish the representation, because we cause the rays to strike the screen at a point where they are less divergent. It is an improvement in exhibiting the representations from the magic lantern, to cause the images to fall on a piece of distended and wetted muslin, behind which the spectators are placed. Lately, the mode of representing scenes has been further improved by using two lanterns, placed at equal distances; in this case, while the view in one is being withdrawn, the view in another is coming on, and the eye is charmed with seeing, for example, a scene in winter dissolve and assume the appearance of a similar scene in summer.

ACOUSTICS.

The term ACOUSTICS is derived from a Greek word which signifies *I hear*, and is applied to that branch of natural philosophy which treats of the nature of *sound*, and the laws which determine its production and propagation.

Atmospheric vibration is allowed to be the cause of sound. For instance, a bell is struck by its clapper—the body of the bell consequently vibrates, as we may

sensibly assure ourselves by applying our nail lightly to the edge: in its agitation, it beats or makes impulses on the air, which, yielding under the stroke or pressure, is compressed or condensed to a certain distance around. The compressed air instantly expands, and in doing so, repeats the pressure on the air next in contact with it; and thus each one of the original strokes of the vibrating metal sends out a series of *shells* of compressed air, somewhat like the waves dispersed over a lake from the dropping of a stone into its placid bosom, and, like them, always lessening in bulk and force. These *shells* are from two inches to thirty feet in thickness. The air, thus agitated, finally reaches the ear, where it gives a similar impulse to a very fine nervous membrane, and the mind then receives the idea or impression which we call a *sound*.

With regard to the velocity with which the impulse of sound advances, it appears, from the most accurate experiments on the discharge of pieces of ordnance, and marking the interval between the flash and the report, at a distance carefully measured, that when the atmosphere is at the temperature indicated by 60° of Fahrenheit's thermometer, sound travels at the rate of 1125 feet per second, which is nearly equal to the velocity of a cannon-ball the moment it issues from the piece. The ball is very speedily retarded by the resistance of the air, but sound advances with undiminished velocity, though unequal intensity. It will travel a mile in little more than four seconds and a half, or twelve and three-fourth miles per minute. On this depends an easy method of determining in many cases our distance from objects, and which may often prove useful, particularly in thunder-storms. We have only to observe in seconds the interval between the flash and the report, and allow four seconds and a half to every mile, or 1125 feet to every second. It is remarkable, also, that all kinds of sounds, strong or weak, acute or grave, advance with the same velocity; and this arises from the circumstance, that all the oscillatory movements in the air, however minute, or however extended, are performed each in the very same interval of time. For every degree of Fahrenheit above 60°, the velocity of sound is increased about $1\frac{1}{4}$ feet, and for every degree below 60°, it is lessened in the same measure; so that when the temperature is at the freezing-point, the rate is only 1090 feet per second.

That air is the vehicle of ordinary sounds is evident from the fact that a bell rung in the exhausted receiver of an air-pump can scarcely be heard. But certain liquids and solids also convey sound, and that with greater velocity and loudness than air. Thus, through water it moves with a velocity of 4708 feet in a second, or more than four times that in air; through tin it is $7\frac{1}{2}$, through copper 12, oak $10\frac{2}{3}$, beech $12\frac{1}{2}$, elm $14\frac{2}{3}$, and through brass and iron $16\frac{2}{3}$ times quicker than in air. A very weak sound—as the scratch of a pin, or the ticking of a watch—made at one end of a log of wood, can be heard by an ear applied at the other end, though it would produce no audible sound at the same distance in air. Savages apply their ear to the ground when they wish to hear any noise that is weak or distant, such as the approach of men or horses. This is the principle of the *stethoscope*. It consists of a wooden cylinder, one end of which is applied to the outside of the patient's chest, the other to the ear of the physician. He is thus enabled to hear the sounds made by the breath in the lungs, and the blood in the heart and blood-vessels, and being familiar with the healthy sounds, can detect any deviations, and thus learns the condition of these viscera.

For transmitting articulate sounds to a distance, *speaking-tubes* are used, by which persons can communicate though in different apartments of a building. The sound is in this case conveyed by the air, and the tube acts by preventing the sound from being diffused and weakened.

In consequence of sound requiring a certain length of time to travel, it is impossible for two sounds, at any distance from each other, to be heard at the same moment by persons who are not at equal distances from both. 'If two persons, A and B,' says an American writer, 'are standing at the distance of one mile from each other, and each fires a gun at the same moment, A will not hear B's gun until several seconds after he hears his own, because the sound will require that time to pass through the distance between them. And the same will be the case with B. One might at first suppose that if A should wait and fire at the moment he hears the report from B, the two sounds would then be heard together. A would hear them together; but the time that must elapse after B had fired, before the sound from A would come to *him*, would be greater than if they fired at the same moment; for he must wait till the sound of his own gun had gone to A, and then until the sound of A's discharge should return to him. It is thus evidently impossible for two persons, standing at a distance from each other, to produce a sound which shall be heard by both at the same time.

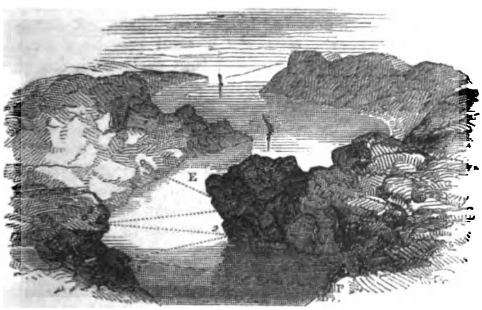
'It is on account of this principle, that in long ranks of soldiers, where two bands of music are placed at a considerable interval from each other, it is impossible for the two bands to keep time with each other. They may indeed play together, but each soldier will hear the nearest sounds quickest, and thus they will seem to be out of time. It is often noticed, too, that if from an eminence we look upon a long column which is marching to a band of music in front, the various ranks do not step exactly together. Those in the rear are in each step a little later than those before them. This produces a sort of undulation in the whole column, which is difficult to describe, but which all who have noticed it will understand. Each rank steps, not when the sound is *made*, but when, in its progress down the column at the rate of 1125 feet per second, it reaches their ears. Those who are near the music hear it as soon as it is produced, while the others must wait till sufficient time shall have elapsed for it to have passed through the air to them.

'Should a commander stand at the distance of a fifth of a mile from his army, and command them to fire, they might all obey at the moment when the word of command reaches them; but the officer will hear the report of the guns from those at the side nearest him first, then those a little further off, and so on to the most remote. Thus, though all might obey with equal alacrity, the sounds will not, and cannot, appear simultaneous, for the reports of the distant guns must be delayed long enough for the command to pass from the officer to the men, and then for the sound to return. All attempts, therefore, to make the firing appear exactly simultaneous from a long line must be in vain.'

An *echo*, or duplication of sound, is one of the most interesting phenomena in acoustics. The cause of it is precisely analogous to the reaction of a wave of water. When a wave of water strikes the precipitous bank of a river, it is thrown back in a diagonal direction to the side whence it came, and there again strikes on the bank. In the same manner, the pulses or waves of sound are reflected or thrown back from flat surfaces which interrupt them, and, thus returning, produce what we call an echo. It is evident that the smoother the surface which reflects the sound, the more perfect will be the reverberation. An irregular surface, by throwing back the wave of sound at irregular intervals, will so confound and distract it, that no distinct or audible echo will be reflected. On the contrary, a regular concave surface will reflect sound in such a manner, that at a certain point the reflections from each part of the concave surface will be concentrated into a focus capable of producing a very powerful effect. The quickness with which an echo returns to the spot where the sound originates, depends of course

upon the distance of the reflecting surface; and since sound travels at the rate of 1125 feet in a second, a rock situated at half that distance will return an echo in exactly one second. The number of syllables pronounced in a second will in such a case be repeated distinctly, while the end of a long sentence would blend with the commencement of the echo.

An echo may be double, triple, or even quadruple, according to the nature and number of the projecting surfaces from and to which the sound is allowed to play. Distinctly marked echoes of this combined order may sometimes be heard in the vaults of cathedrals, in which case the waves of sound are driven from side to side of a deeply groined arch, and reverberate in protracted peals. One of the most interesting echoes of this kind in nature, is that which occurs on the banks of the Rhine at Lurley. If the weather be favourable, the report of a musket, fired on one side, is repeated from crag to crag on opposite sides of the river alternately, as represented in the figure; where P is considered as the



primary point of radiation for the sound, which crossing the river, strikes at 1, then is sent off to 2, and so on to 3 and subsequent points, stopping, or faintly dying away, opposite E.

There are some remarkable echoes in ecclesiastical structures, arising from peculiarities in the construction. In erecting the baptistry of the church of Pisa, the architect, Giovanni Pisano, disposed the concavity of the cupola in such a manner, that any noise from below is followed with a very loud and long double echo. Two persons whispering, and standing opposite to each other, with their faces near the wall, can converse together without being overheard by the company between. This arises from the elliptical form of the cupola, each person being placed in the focus of the ellipse. In the cathedral church of Gloucester, there is a whispering-gallery above the eastern extremity of the choir, which extends from one end of the church to the other. If two persons, placed at considerably distant points, speak to one another in the lowest voice, it is distinctly heard. A similar effect is produced in the vestibule of the Observatory of Paris, and in the cupola of St Paul's in London. A tourist has mentioned that in Italy, on the way to Naples, and two days' journey from Rome, he saw in an inn a square vault, where a whisper could easily be heard at the opposite corner, but not at all on the side-corner that was near to you. This property was common to each corner of the room. He saw another on the way from Paris to Lyon, in the porch of an inn which had a round vault. When any one held his mouth to the side of the wall, his whisper could be heard on the opposite side.

The whispering-gallery in St Paul's, London, is a great curiosity. It is 140 yards in circumference, and is just below the dome, which is 430 feet in circumference. A stone seat runs round the gallery along the front of the wall. On the side directly opposite the door by which visitors enter, several yards of the seat are covered with matting, on which the visitor being seated, the man who shews the gallery whispers with the mouth near the wall, at the distance of 140 feet from the visitor, who hears his words in a loud voice, seemingly at his ear. The mere shutting of the door produces a sound like a peal of thunder rolling among the mountains. The effect is not so perfect if the visitor sits down half-way between the door and matted seat, and much less if he stands near the man who speaks, but on the other side of the door.

It is of great importance that buildings designed for large auditories should be constructed in such a manner that the voice of the speaker will neither echo from the walls nor be lost to the hearers. The best known form of apartment for the proper distribution of sound, is that in which the length is from a third to a half more than the breadth, the height somewhat greater than the breadth, and having a roof bevelled off all round the sides. This species of ceiling, called technically a coved or *coach roof*, from its being lower at the sides than centre, is in all cases best suited for conveying sounds clearly to the ears of auditors.

MUSICAL SOUNDS.

There is a peculiar character in sounds, depending on the character of the sounding body. A blow with a hammer, or the report of a pistol, produces only a noise. But if a body be of such a thinness and tightness as to produce a succession of impulses of a sufficient degree of quickness, a *tone* is the result—namely, a sound composed of a great number of noises, all so close upon each other, that they bring but one result to the ear. Wires and strings of metal and catgut, slips of metal, fine membranes, and columns of the air itself enclosed in tubes, are the most familiar means of producing sounds of this kind. Such sounds are said to be musical.

The study of musical sounds, as a branch of natural philosophy, is calculated, perhaps, to give as much pleasure to the man of science as music itself can convey to those who are gifted with what are called good ears. The natural character of these sounds, and their relations to each other, are very remarkable; while the relation of the whole to the human mind must be regarded as one of the most interesting proofs of creative design which the entire circle of nature presents.

The principal sounds of music may be said to be only seven in number. There are other five, which may be produced by the voice with some little difficulty; but the voice, in an untutored condition, gives forth only seven. The notes are of different degrees of shrillness, one rising above another in succession. A person who knows nothing of music beyond having heard another sing or play, and having seen the key-board of a pianoforte, will be ready to say that there are more notes than seven; but there are only seven that are, strictly speaking, various. The voice, or an instrument, may run up into other notes; but all of these are repetitions of the first seven, and identical respectively with them, in all respects except shrillness. In ordinary pianofortes, there are at least six repetitions of the seven notes, so that the uppermost keys are shriller than the voice of a child, while the lowest rumble like a drum.

The seven notes are named *Do*, *Re*, *Mi*, *Fa*, *Sol*, *La*, *Si*, or by the first seven letters of the alphabet in a peculiar arrangement—namely, C, D, E, F, G, A, B. They

are here represented in the well-known language which musicians present to the eye (using the *treble clef*).

Let an ordinary piece of catgut or violin string be extended between two points on a board, and screwed up. It may be made, according to its length and degree of tension, to vibrate, when struck, exactly 240 times in

a second. The note which it thus produces is C, or Do; and a man, on trial, will find that this is the note with which he is most apt to begin a song, when he attempts to sing. The note in his voice will be perfectly in unison with the note produced by the string; that is to say, they will melt into and agree with each other, and the effect will be pleasant. This is because the membrane at the top of the singer's windpipe (the instrument of his voice) vibrates exactly the same number of times in a second, producing that note, as the string does. The equality in the number of vibrations is what makes the notes the same, and the effect harmonious and agreeable.

We shall suppose the string to be forty-five inches long that produces the note C of 240 vibrations in a second. Being extended between two pegs near the surface of a board, the experimenter may place his finger upon it right in the centre, and twang or strike either half, when he will find a much shriller note produced, being, in reality, the first C, or Do, of a new series of the seven notes. In this case, the vibrations are exactly double—namely, 480 in a second—these being always the more rapid the shorter the string or the greater its tightness. The second or upper C is called the *octave* of the first, being the eighth note above it.

We shall now suppose that the string is shortened only so far as to leave thirty inches, or two-thirds of its length, free for twanging. This shorter string will sound the note G, or Sol. In this case, as the length of string is two-thirds, so are the vibrations three-halves, or one and a half times those in the former instance; namely, 360. All the other notes are produced by different proportions of string and numbers of vibrations, as shewn in the adjoining scale.

- C or Do (octave), 22½ in. 480 vib.
- B or Si, 24 in. 450 vibrations.
- A or La, 27 in. 400 vibrations.
- G or Sol, 30 in. 360 vibrations.
- F or Fa, 33¾ in. 320 vibrations.
- E or Mi, 36 in. 300 vibrations.
- D or Re, 40 in. 270 vibrations.
- C or Do, 45 in. 240 vibrations.

What is remarkable here is the curious mathematical proportions on which the various notes depend. Taking the first C as one, and its octave as one-half, we have various lengths of string for the intermediate notes, in the following proportions:—namely, for D, eight-ninths; for E, four-fifths; for F, three-fourths; for G, two-thirds; for A, three-fifths; and for B, eight-fifteenths; all of which proportions are exactly reversed with regard to the numbers of vibrations, these being in succession nine-eighths, four-fifths, &c. The proportions, as clearly appears to the eye from the above scale, are not regular: the string is first shortened five inches, then four, then two and a quarter, next three and three-quarters, and so on. Nevertheless, these are the musical notes which the voice naturally gives forth, and which the mind recognises as beautiful. The string twanged at lengths which would appear in more regular proportion, would give forth musical sounds, but not the seven notes of music—not those peculiar sounds which all nations recognise as such, and which nature has manifestly appointed to serve in that character.

Irregular as the proportions appear, there are some of the seven notes which are more proportioned to each other than the rest. They are said to be more in *harmony* with each other; and the effect when they are struck together is pleasing. It is to be observed, in the first place, that a note always harmonises well with its *octave*, or the eighth or repeating note above it. This is supposed to be because the vibrations of the one note in that case are exactly two for one of the other. The first Do also harmonises well with Sol (G), which is called its *fifth*, being the fifth note above it; and this is, on the same supposition, because the vibrations are in that case as three to two, which is also a symmetrical proportion. Harmony is also produced when some other notes are sounded at the same moment with those which are third above them (their *thirds*); and this may be accounted for in a similar way. Thirds, fifths, and octaves are, therefore, pleasing or harmonious sounds; while seconds, fourths, sixths, and sevenths are less so.

Experiments of a very curious nature have been made on this subject. It may readily be observed by the naked eye, that when one of the longer strings of the harp or pianoforte is struck, there is not only a vibration along the whole length, giving it an elliptical appearance, but there are also vibrations of shorter lengths of the same string going on at the same time. It has been found, when light pieces of paper are hung across the string, that they settle at certain places, shewing that the principal subordinate vibrations correspond with octaves, fifths, and thirds. A drum, or a sonorous board, over which sand has been strewn, will, if beat, throw the sand into curious figures of a determinate and regularly recurring character. There are even more curious facts connected with the harmonious notes. The *cries* of a city—that is, the scarcely articulate, but often very musical, sounds uttered by persons selling things on the streets—generally rise on thirds or fifths, sometimes on octaves; and this although few of these poor people have ever been taught music. The cry of oysters by women in Edinburgh is, for example, always on an octave.

With respect to the sounds produced by wind-instruments, the effect is caused by the vibrations of a column of air confined at one end, and either open or shut at the other. The length of the sounding column determines the nature of the vibrations; but along with the fundamental tone, there are interior and subordinate vibrations. The whole column divides itself into regular portions—equal to the half, the third, and so on, of the longitudinal extent—in the same manner as we shewed was the case in stringed instruments. We may observe something similar to these vibrations in the contraction and expansion of a long and very elastic string, to one extremity of which a ball is attached. A spiral spring also shews, and perhaps more clearly, the repeated stretching and recoil. If suddenly struck at one end, it will exhibit not only a vibration throughout its whole extent, but likewise partial ones, which wind vermicularly along the chain of elastic rings. If the air be struck with great force, the subordinate vibrations sometimes predominate, and yield the clearest and loudest tones. This may be observed in the dying sounds of a bell, which rise one or two octaves, and expire in the acutest note. Upon the degree of force with which the instrument is blown, depends the performance of the bugle-horn, whose compass is very small, consisting only of the simplest notes. In other wind-instruments, the nature of several notes produced depends upon the length and size of the tube, or the positions of the holes in its sides. In the organ, there is a pipe for each note, and wind is admitted from the bellows to the pipes by the action of keys similar to those of a pianoforte. The organ may be played also by a barrel made to turn slowly under the keys, and to lift them in passing, by means of pins projecting at certain determinate intervals from the surface of the barrel. In wind-instruments which are furnished with reeds, the tone depends on the stiffness, weight, length, &c., of the vibrating plate or tongue of the reed, as well as on the dimensions of the tube or space with which it is connected.

ELECTRICITY—MAGNETISM—ELECTRO-MAGNETISM.

ELECTRICITY.

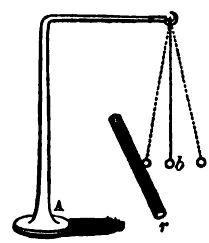
IT was observed in ancient times, that when amber was rubbed, it acquired a power of attracting and repelling such light bodies as hair and feathers; and this power afterwards came to be called ELECTRICITY, from *electron*, the Greek word for amber. Although the ancients were thus familiar with some of the more obvious phenomena of electricity, they did not investigate the subject methodically, or attempt any generalisation of facts into a scientific theory. It was only in modern times, when close reasoning from truths, established by the evidence of the senses, began to be practised by philosophers, that the phenomena connected with electricity assumed the dignity of a science. Dr Gilbert, an English physician, made the first step towards generalisation in the year 1600. He published a valuable treatise, in which he observed that not only amber, but various other substances, can, by friction, be made to draw light bodies to them. Boyle, Guericke, Newton, and some other philosophers of that period, contributed to extend human knowledge upon this interesting subject; but the real science of electricity took its rise in a later age. About the middle of the eighteenth century, several very remarkable facts were ascertained, particularly by Benjamin Franklin, which identified lightning with electricity; but the extensive relations which connect it with so many other departments of physical science were not discovered until the present century, nor was their importance until then appreciated. In this short era, a new science has arisen, founded on that modification of electricity which is known by the name of VOLTAIC ELECTRICITY. The voltaic battery (which will be afterwards described), as an instrument for analysing or decomposing chemical substances, has connected it with chemistry in the most intimate manner. Hence has sprung ELECTRO-CHEMISTRY, one of the connecting branches between remote divisions of the philosophy of nature. ELECTRO-MAGNETISM is a still more recently discovered province of science, and which identifies as one two powers which were previously regarded as distinct.

The general facts relating to this subject may be classed under two heads—1*st*, The *Excitation* of Electricity; and 2*d*, The *Distribution* of Electricity. Connected with each of these heads are various phenomena, which we shall notice as they occur during the gradual development of the subject.

EXCITATION OF ELECTRICITY.

If a stick of sealing-wax, a bit of amber, the glass of a watch, or any other smooth piece of glass, be rubbed upon dry flannel or woollen cloth, or even the sleeve of a cloth coat, it will be found to have acquired a new and very singular physical property. This property is exhibited by holding the body which has been subjected to friction over small and light substances, such as shreds of paper, goldleaf, feathers, straw, cork, &c. These will be first instantly *attracted* to it, some of them adhering to its surface, others falling back to the place whence they were withdrawn, whilst others are thrown off from the body, as if they were *repelled* from it. Here, then, is a distinct phenomenon—a process of attraction and repulsion at the same instant, which requires careful examination.

The phenomena of attraction and repulsion may be exemplified in a striking manner by a small apparatus, of which we adjoin a representation. A is a stand bent at its upper extremity, and having a hook to which a fine silk thread is attached, with a very small pith-ball at its end *b*. Rub a dry rod of glass *r*, and, on presenting it to the ball *b*, the ball will be immediately attracted to the glass, and will remain in contact with it. After they remain in contact for a few seconds, if the glass be withdrawn without being touched by the fingers, and again presented to the ball, the latter will be *repelled*, instead of being attracted, as in the first instance. By being touched with the finger, the ball can be deprived of its electricity; and if, after this has been done, we present a piece of sealing-wax in place of the glass formerly employed, the very same phenomena will take place: on the first application, the ball will be attracted; and on the second, repelled. It is clear, then, in the first place, that both these electrics—the glass and the wax—have the power of attracting another body before they have communicated to it any of their own electricity; and, secondly, that they repel the body after they have communicated to it a portion of their own electricity.



But a very remarkable circumstance takes place, if we, after having conveyed electricity to the ball *b*, by means of excited glass, which has been for a moment or two in contact with it, should present to it, after the former was withdrawn, excited sealing-wax: the ball, instead of being *repelled*, as it would be were the glass again applied, is *attracted* by the wax. If the experiment be reversed, and the excited wax first presented to the ball, and then the excited glass, the latter will be found to attract the ball. 'Hence it follows,' says Sir David Brewster, 'that excited glass *repels* a ball electrified by excited glass. Excited wax *repels* a ball electrified by excited wax. Excited glass *attracts* a ball electrified by excited wax. Excited wax *attracts* a ball electrified by excited glass. From which we conclude that there are two opposite electricities—namely, that produced by excited glass, to which the name of *vitreous* or *positive* electricity has been given; and that produced by excited wax, to which the name of *resinous* or *negative* electricity has been given.

'If, when the pith-ball *b* is electrified, either with excited glass or wax, we touch it with a rod of glass, its property of being subsequently attracted or repelled by the excited glass or wax will suffer no change; but if we touch it with a rod of metal, it will lose the electricity which it had received, and will be attracted either by the excited glass or wax, as it was when they were first applied to it. Hence the rod of glass and the rod of metal possess different properties—the former being incapable, and the latter capable, of carrying off the electricity of the pith-ball.'

In these experiments, electricity has been produced by *friction*; but there are other methods of obtaining it, which, however, will be afterwards explained.

With regard to attraction and repulsion, a few facts remain to be stated. Some substances remain longer in contact with the electric than others, and two bodies which have both been in contact with the same electric mutually repel each other. If electrics of considerable size are employed, the phenomena of course are better observed; and if the experiment be performed in a

darkened chamber, flashes of bluish light will be seen to extend over the surface of the electric submitted to friction, which we shall suppose is a cylinder of sealing-wax, sulphur, or glass. Sparks, accompanied also with a sharp snapping sound, will be seen to dart round it in various directions. If a round body, as a metallic ball, be presented to it, and moved from one end to the other, a succession of sparks will be obtained as the ball passes along the surface; and if the knuckle be presented, instead of the metallic ball, each spark will be accompanied by a pricking sensation. If a metallic globe be suspended in the air by silk threads, and in that situation rubbed by an electric, it will also become electrical, and exhibit the same properties as an electric. It is essential to the success of this experiment that it be *insulated;* that is, cut off, by means of a non-conductor, from all communication with any substance, except the air and the electric which sustains it.

DISTRIBUTION AND TRANSFERENCE.

We have noticed that when the excited electric was brought near the pith-ball *b*, the latter was first attracted, and then repelled. If we now remove the electric, and present to the ball which has thus touched it, a second ball which has had no previous communication with an electric, we find that these two balls attract one another, and come into contact. The same actions are repeated between this second ball and a third which may be presented to it; and so on in succession, but with a continued diminution of intensity. This diminution plainly indicates a diminished power, in consequence, as it would seem, of its being distributed amongst a number of bodies. It is clear, therefore, that the unknown power which we have called electricity can, like heat, be transferred or communicated from one body to another, and that its intensity, like that of heat, is weakened by being diffused amongst a number of bodies. An electrified ball can be deprived of its electricity by being touched with a rod of metal of any kind; but if we touch it with glass or wax, it will not be carried off. Hence, metals are said to be *conductors*, and glass and wax *non-conductors*, of electricity. Non-conductors obstruct the passage of electricity, and are therefore called *insulators*, because they coop up the electricity where it is, as in an *insula* or island.—It is to be observed that electricity is not conducted through the substance of bodies, like heat, but is confined entirely to the surface.

There is no absolute distinction between conductors and non-conductors; they differ only in degree. The excitement runs along the surface of a metal with inconceivable rapidity, but even metals have been proved to offer some obstruction, and to retard its passage in an appreciable degree. Wax and glass, again, do not entirely prevent the passage of electrical excitement. All bodies, then, are conductors in a greater or less degree, and the worst conductors are the best insulators.

In the following list, the bodies are arranged in the order of their conducting power, beginning with the best and ending with the worst:—

All the metals, charcoal, strong acids, saline solutions, water, living vegetables and animals, damp air, flame and smoke, alcohol, moist earth and stones, oils, ashes, lime, porcelain, dry vegetable bodies, dry gases and air, feathers, hair, silk, gems, glass, wax, sulphur, resins, amber, shell-lac, gutta-percha.

This list becomes one of insulators if read backwards, the best insulators standing last—gutta-percha, shell-lac, &c. In the middle of the list, conductors and non-conductors merge insensibly into one another. The conducting power of water, though not the highest, is still great, and hence the very best insulators become conductors when wet or damp. Water becomes a very imperfect conductor when in the state of ice below 13°, or in that of dry steam. Glass, from its solidity and strength, is much used as an insulator, though it is inferior to the resins, especially shell-lac. Insulators made of other substances are often coated with lac, which prevents the deposition of moisture. A cotton or linen thread may be reckoned a conductor, though imperfect; silk is used as a non-conductor. Air, it is clear, must be a good insulator, otherwise the electricity, when excited, would speedily disappear from the surface of bodies, which is not the case if the air be dry. Temperature affects the conducting power of bodies; glass heated red becomes a conductor, and so do resins when melted. The metals, again, conduct less perfectly when heated.

It was formerly considered that the insulators were the only bodies that electricity could be excited on; hence they were also called *electrics*, while the conductors—such as the metals—were called *non-electrics*. But this supposition is false. The metals are excitable by friction the same as the resins; but, from their being good conductors, the electricity is apt to disappear from their surface as fast as it is formed. It is possible, by proper insulation, to make them electric, as well as sealing-wax or glass. In the electrical machine, the electricity is produced by the rubbing of a metallic surface on glass. The distinction of electrics and non-electrics, therefore, is no longer admitted.

The earth is considered the general reservoir of electricity: whenever any excitement is connected with the ground by a good conductor, it passes thither, and is lost by dissipation, like a wave spreading out on a boundless sea. The earth is generally neutral, or very slightly charged: and electricity of high tension will always run towards a body with either no charge, or with a feebler charge, and still more with an opposite charge.

When an electrified surface, or an electric charge of any kind, has two connections with the ground, or with neutral surfaces where it can spread, it always passes by the best conductor, even although this should be by far the longest path. Thus, a metallic rod would be preferred to a line of water, water to dry wood, and wood to glass.

THE TWO KINDS OF ELECTRICITY.

It will be understood, from the preceding explanations, that there are two kinds of electricity—namely, a *vitreous* or *positive* electricity, and a *resinous* or *negative* electricity. Although we have thus two electricities, there does not appear to be the smallest difference between them when they are taken individually. The distinction is only observable when brought in contact; they then display so marked a contrariety, or mutually opposive force, that they may be viewed as agents having opposite qualities, which completely neutralise one another by combination, just like an acid and an alkali. It is remarkable that the excitation of one species of electricity is always accompanied by the presence of the other, and both are produced to an equal extent. Thus, when a piece of glass is rubbed by silk, just as much resinous electricity is produced in the silk as there is vitreous electricity produced in the glass; and whatever electrified bodies are repelled by the one, are attracted by the other. Of course these two surfaces, having acquired opposite electricities, invariably attract each other. A white and a black ribbon rubbed against each other between the finger and thumb, exhibit electrical phenomena in a very marked manner. The black is resinously, and the white vitreously electrified: of course they attract each other; and if separated, the one attracts the light bodies which the other repels. When two pieces of the same ribbon of the same length are rubbed, the one being drawn lengthways, and at right angles, over a part of the other, the one which has been subjected to friction in its whole length acquires vitreous, and the other resinous electricity.

In performing these and other experiments, an instrument is used called the *electroscope.* A gold-leaf electroscope is represented in the annexed figure. It consists of a glass vessel, into which is inserted a metallic rod, terminating in two gold leaves, and surmounted by a metallic plate. If the plate is touched by a body, however slightly electrified, the excitement passes down to the leaves, and causes them to repel each other, or *diverge.* An instrument with means of measuring the amount of divergence is an *electrometer.* If the leaves of the electroscope are made divergent, say with negative electricity from sealing-wax, when another excited body approaches, it will be at once apparent which kind of electricity it has got: if negative, the leaves will continue to diverge; if positive, they will collapse.

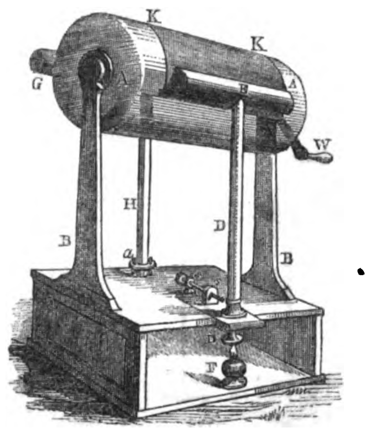
No general law has yet been discovered enabling us to say before trial which of two substances rubbed together will be positive, and which negative. The fur of a cat is rendered positive by friction with every substance that has yet been tried; and smooth glass is also rendered positive by every substance, except cat's fur. Sulphur, on the other hand, has a similar tendency to become negative, whatever it be rubbed with. In general, it is observed that hardness in a body predisposes it to receive positive electricity, as does also smoothness. If two pieces of the same material are rubbed together, the one being rough, and the other smooth, the rough one will be negative, and the other positive. The one in general that takes most heat from the friction is negative. But experiments with the same substances sometimes give opposite results.

In rubbing metals to produce electricity, it is necessary to rub with large sweeps, to prevent the two electricities from joining together at the instant. The conducting power of the metals is such, that the excitements produced on the touching surfaces are very apt to run together, and neutralise each other on the spot.

Electrical phenomena are generally accounted for by supposing that there is an extremely subtile and highly elastic fluid which pervades all material substances, but is itself devoid of any sensible gravity. It is supposed to move with various degrees of facility through the pores or actual substance of various kinds of matter. Hence, in proportion as they admit of the fluid passing through them with ease or difficulty, bodies have been divided into conductors and non-conductors. According to the doctrine of there being but one species of fluid, it is supposed that the electrical equilibrium which constitutes the natural state of matter, is disturbed by friction, and that one of the two bodies brought near to each other attracts to itself a surcharge of the fluid, and is *over-saturated,* whilst the other is left in a deficient state, and is *under-saturated.* For this view of the subject we are indebted to Franklin; and hence the terms of positive or plus, and negative or minus, have arisen. But as some of the appearances cannot easily be reconciled to the hypothesis of a mere excess or deficiency of one fluid, there is another theory which supposes the fluid to be a *compound,* susceptible of decomposition by friction and other means; hence the origin of the terms vitreous and resinous electricities. With respect to the intensity of the electric force, it resembles that of gravitation, by being inversely as the square of the distance. Like gravitation, also, it acts at all distances, and it is not impeded by any intervening body, provided it be not in an active electrical state. But whilst the particles of each fluid repel those of the same kind, they exert, as we have seen, a high attractive power over those of an opposite kind. The intensity of this attraction also, like that of gravitation, increases with a diminution of distance. It is evident, therefore, that from the powerful attraction which they have for each other, they would always flow towards each other, and coalesce, were it not that the non-conducting properties of electrics offer an impediment to their motion.

ELECTRICAL MACHINE.

In order to procure electricity in large quantities, and of great intensity, a rubbing-machine is constructed, called the Electrical Machine. Its essential parts are *a cylinder of glass,* mounted on an axle on which it may be turned, a *cushion* covered with a metallic paste, and a *metallic cylinder* to take the electricity off from the glass. The figure represents such a machine. AA is the glass cylinder, revolving on an axis in the two supports B and B, which are either of wood or glass. E is a cylinder,



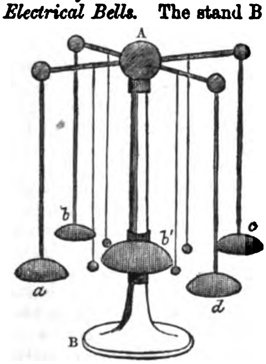
carrying the cushion that rubs on the glass. This cushion is commonly separable from the cylinder, and when placed in it, rests on a spring, which keeps it close to the glass during the friction. The cylinder E has a metallic surface of brass or tin, and it is supported on a pillar D, which is an insulator made of glass. On the other side of the glass cylinder is the metallic cylinder G, destined to receive the electricity evolved on the former. It does not of itself rub on the glass, but it is armed with a row of brass points, which almost touch the excited cylinder, and which are specially adapted to carry off the electricity, and spread it over the metallic surface. This cylinder is called the Prime Conductor, or first receiver of the excitement, and it is supported by a glass pillar H, in order to be insulated. As the electricity of glass is positive, this cylinder must always receive positive electricity; hence it is called the Positive Prime Conductor. Since the cushion cylinder gets itself charged with negative electricity, it is called the Negative Prime Conductor. The base of the pillar supporting the negative conductor is movable by a screw *aa*, to regulate the pressure of the cushion. A flap of silk, KK, is fastened to the upper edge of the cushion, and covers the upper half of the cylinder; this may both increase the friction given to the glass, and help to retain the electricity on the surface till it go round to the points on the prime receiver. The surface of the cylinder and of the insulating pillars must be kept warm and dry during the working of the machine; and for this purpose a permanent heating body is sometimes kept near, such as an iron heater or a lamp, F, applied to the hollow, D, of each glass pillar. Although the cushion cylinder is on an insulating stand, it is not generally insulated when the machine is worked; insulation is used merely for certain special experiments. Accordingly, it is usual to connect the negative cylinder with the ground by a chain. If it were not so connected, it would become highly

charged with negative electricity, and resist the further disengagement of the excitement.

The metallic paste smeared upon the cushion—a hair-cushion covered with chamois leather—is an *amalgam*, or mixture of six parts of mercury, two of zinc, and one of tin. It is spread on the cushion with a knife, and requires to be renewed from time to time.

The operation, then, consists in turning the cylinder rapidly by the handle W. Its surface is rubbed hard on the metallic paste, which the cushion is smeared with, and electricity is evolved of both kinds. The positive excitement appears on the glass, and is carried round and taken off by the points of the prime conductor, and there accumulated, being cut off from all conducting communication with the ground. The negative excitement is given to the metallic coating of the cushion, and thence to the whole of the negative cylinder; but for the sake of getting additional excitement from the machine to the other side, this is carried to the earth by the chain.

A great number of striking and beautiful experiments can be made by electrifying bodies, and making them display the attractions and repulsions caused by the electricity. One of the most interesting is that with the *Electrical Bells.* The stand B carries upon it at a little height a bell b', and above the bell a glass insulating rod terminating in the brass knob A. From A proceed four brass rods, and from their extremities are suspended by brass rods or chains four bells, a, b, c, d, hanging on a level with the bell b' on the pillar. Four brass balls are suspended by silk threads from the arms running out from A, so as to hang between the outer bells and the central one. Electricity is then conveyed from the prime conductor of the machine to the central knob, or to any of the arms, and runs over the whole of the arms and the outer bells; but it is prevented by the glass pillar from passing to the middle bell, and by the silk threads from passing to the brass balls. The outer bells are therefore highly charged with the electricity of the positive prime conductor, and each attracts the ball next it. The balls move up, therefore, and strike the bells; but no sooner touch them, than they are repelled, and fly in the direction of the central ball; which, being neutral and uninsulated, takes off their electricity, and with it their repulsion from the outer bells; so that the instant they strike upon the neutral centre, they are again attracted to the electrified bells, and immediately repelled as before. Thus, by incessantly swinging between the two, they keep up a tinkling as long as the electricity continues.



Another set of experiments on the same principle is made by feathers, heads of hair, or like bodies. When these are electrified, the repulsion that bodies in the same state always manifest, causes the hair to bristle up, and spread itself out as far apart as possible.

Another form of the electrical machine, more powerful than the one just described, is what is called the Plate Machine—that is, instead of a cylinder, a flat circular plate is used. The cushion must then be double, so as to hold the edge as between one's finger and thumb; and the other parts must correspond to the shape of the glass. Two rubbers and two sets of points are commonly applied to the plate's edge, dividing it, as it were, into four quarters. The objection to such machines is their liability to crack, by the heating that all machines must undergo to make them thoroughly dry before being wrought.

A machine of great power has been constructed, which receives the name of Armstrong's Hydro-electric Machine. It was observed by Mr Armstrong, that a jet of steam rushing out from an iron boiler, made the boiler give off electric sparks, shewing that it had been electrified by this action. Accordingly, iron cylinders have been formed like the boilers of steam-boats, and mounted with tubes for the escape of the steam in the form of jets. The steam is raised to a pressure of two or three atmospheres before the tubes are opened. It is then allowed to rush out in a row of jets, and in doing so it communicates *negative* electricity in great quantity, and of a very intense kind, to the whole outer surface of the boiler, while it is itself positively electrified in an equal degree. The boiler being supported on glass pillars, in order to be insulated, becomes so intensely charged that, if not relieved, it darts off sparks to great distances. No rubbing-machine can equal such an apparatus in power.

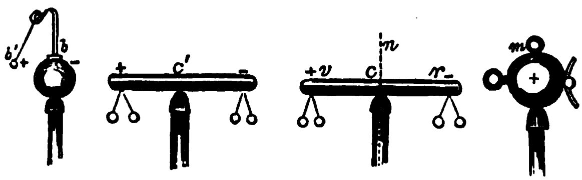
The mode of action in this machine has been thoroughly investigated and explained by Faraday. He has shewn that the electricity arises from the friction of water-globules against the edge of the steam-holes. When the steam rushes out at high-pressure, it carries a shower of water-particles with it, and these act as a rubber upon the metallic surface of the boiler; and the strong friction between water and iron is the source of the electricity. If the steam is dry—that is, if it is perfect steam, or the true elastic gas of water, and free from cloudy or watery particles—it produces no excitement whatever. If atmospheric air, or any other dry gas be used, there is no electricity excited; and it is completely proved that a gas can in no case serve as a rubber to evolve electricity. But if the gas carry with it a shower of particles either *solid* or *liquid*, the surface that it rushes through becomes electrified, and the solid or liquid particles acquire the opposite excitement. It depends upon the substance used what is the kind of electricity given to the metal. The iron boiler is made negative by the water-particles in the steam-current; but if we substitute for water oil of turpentine, olive-oil, resin, or other similar bodies, the solid rubbed by them is positive, and the jet negative. Either steam or dry air may be used to carry the powder, the gas having no action but to sustain the rubbing stream. The action ceases if the water-drops contain any trace of acid or salt, which would render them much better conductors of electricity than drops of pure water. It is from its being too good a conductor, that a metal cannot be electrified by ordinary rubbing, like a piece of amber or wax. But the rapid rush of watery particles succeeds in charging even a metallic surface. If, however, the water is rendered too good a conductor, by an acid or a salt being dissolved in it, the difficulty of keeping the electricities apart is rendered so much greater.

INDUCTION.

It has been seen that when electricity is evolved, both kinds are formed at the same time. The one of the two rubbed bodies has a positive charge, the other an equally strong negative charge. The same principle extends further: we find that a charge cannot even exist on a surface unless there be on some adjoining surface an equal and opposite charge. Positive electricity cannot be insulated, and made to remain by itself; it will not pass into any situation where it cannot be accompanied with a counter-charge of negative excitement. The polar character is rigorously sustained in frictional electricity, as well as in magnetism; we can no more have one kind of excitement alone by itself, than we can have a magnet all north or all south.

When a surface charged with electricity of one kind is in the neighbourhood of other surfaces, but not touching them, it communicates to them the *opposite* electricity. The apparatus best adapted for demonstrating this is a set of brass cylinders rounded at the ends, and placed on insulating stands. Thus, let m be the prime-conductor of a machine; c and c' two insulated

cylinders laid end to end at a little distance from each other and from the conductor; and *b* a brass ball, with a pith-ball *b′* suspended to it. When the machine is wrought, the whole of the surface of *m* has positive



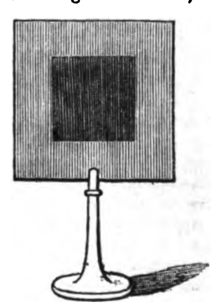
electricity. Now the action of *m* upon the adjoining cylinder is such, that the nearest end *r* is electrified negatively, and the remote end *v* electrified positively. The cylinder has received no electricity by conduction; it has become polarised by induction, exactly as happens in magnetism. The middle, *n*, is neutral, and the two ends are charged with equal and opposite excitements. But this cylinder exerts its action on the second cylinder in the same way; the end of which next *v* is negatively charged, and the other end positively charged. The ball *b* also is affected by the positive end of the second cylinder, and made negative at one side, and positive at the other, where it repels the pith-ball. Thus the prime conductor, without parting with any of its excitement by *conduction*, polarises a series of bodies by its *inductive* power. There is no limit to the number of bodies that might thus act on each other, except the tension of the conductor; but the action on each successive surface becomes gradually feebler.

If the remote end of one of the cylinders is connected by a conductor with the earth, the charge on that end passes off to the earth, and the opposite electricity spreads over the whole surface of the cylinder. Thus, if the positive excitement of *v*, the far end of the first cylinder, were conducted away, the cylinder would possess all over a negative charge, as if it had been connected with the negative prime conductor of the machine. But if, on the other hand, without conducting off any portion of the induced electricity from any of the surfaces, we withdraw the prime conductor *m*, whose tension caused the succession of polarities, they all instantly return to their original neutral condition. The presence of the primitive source is necessary to sustain the action; and when this fails or is cut off, it is like the removal of a magnet from a soft iron bar—the temporary excitement ceases.

We may now understand why an electrified surface attracts a neutral or unelectrified body, such as a pith-ball. It is not that electricity causes attractions between excited and unexcited bodies, the same as between bodies oppositely excited; but that the pith-ball is first rendered opposite by induction, and attracted in consequence of this opposition. A pith-ball at a few inches' distance from an electrified surface is charged with electricity by induction; and the kind being contrary to the kind of the surface, attraction ensues; when the two touch, they become of the same kind by conduction. The case of attraction by excited surfaces is the same as the magnet's attraction for iron: an opposite excitement is first communicated to the body, and it is then attracted. If a series of cylinders were electrified as above shewn, they would all tend to attract each other by their opposite poles.

It is a fact only lately discovered, that neither the prime conductor of the machine, nor any surface whatever, can receive or contain electricity, unless there be other surfaces near to contain an opposite charge of the induced kind. Whatever bodies are in the neighbourhood, the walls and furniture of a room, &c., are made use of for this purpose, as well as anything that is casually brought near. If the surrounding surfaces are easily excited, and can take on the induced electricity well, the prime conductor of the machine, or any connected surface, may acquire a high charge; but if these surfaces are difficult to excite, if they are of the non-conducting kind, the prime conductor will receive only a feeble charge. The second pole is in this case not readily observable—it has a sort of irregular character; but decisive experiments were made by Faraday, which proved that where there is not a confronting surface for the induced charge, it is impossible by the most powerful machine to put the least possible excitement on any surface whatever. It had previously been shewn, that if the outer surface of a hollow sphere were charged, no electricity would pass to the inside, although there were a free communication by holes; and Faraday put the thing to the test on a large scale, by constructing an insulated room, which he went into with his electroscopes, while the outside was charged by a large machine; whereupon it was found that no trace of excitement appeared in the inside. The reason is, that there is not room in the interior of a continuous hollow surface for both excitements to exist apart, and yet confront one another.

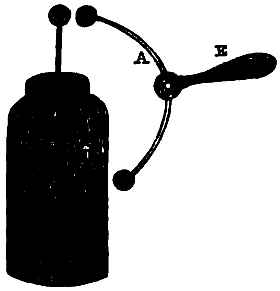
There is a limit placed to the accumulation of electric excitement on any surface. But the better the opposition surface given for the induced electricity, the higher the charge that it is possible to communicate. Accordingly, an apparatus was devised last century by a Dutchman of Leyden, thence called the *Leyden-jar*, which completely suits the polar nature of the charge by providing two equal surfaces, held apart by an insulating medium, to receive both the primary and the induced electricity. The simplest form of this double-surface apparatus is a pane of glass, with a coating of tinfoil on each side, the coatings being equal to one another, and smaller than the glass, so as to leave an uncoated margin all round, as represented in the figure. If one of the coatings is connected with the machine, and positively charged, it will act by induction through the glass upon the other coating, and excite it in the manner already described in the case of the row of brass cylinders. The near or inner surface of the second coating will be made negative, and the other surface positive; and if the coatings are insulated, this state will continue. But if the outer



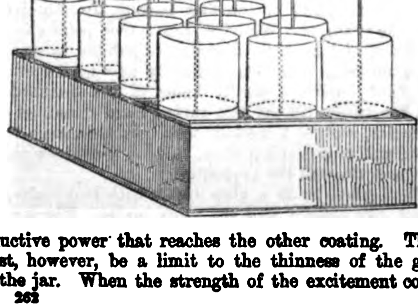
side of the second coating is connected with the ground, and the positive induced charge taken off, the surface will have only a negative charge left corresponding to the positive charge of the first coating, directly derived from the machine. We have thus a true polar charge—a positive and a negative surface separated by an insulating medium. The excitement is now no longer *free*, but *fixed;* and we hardly know of the accumulation that has arisen, till the two surfaces are connected by a conductor, such as a metallic wire; we then see a bright spark, and hear a sharp snap, as if a violent shock had been sent through the apparatus.

The Leyden-jar is a glass bottle with two coatings of tinfoil, one outside, and the other inside. The coatings do not reach to the mouth of the bottle, so that they leave a rim of naked glass. A plug is fitted tightly into the mouth, and covered with varnish, and through the

middle of it a brass rod is passed, with a chain hanging to its lower end, to make a connection with the inner coating. The upper end of the rod is formed into a round knob. The figure represents the jar with the apparatus used for discharging it; which last is a glass rod, E, to hold in the hand, and two brass arms connected at A by a movable joint. Through these two arms the two electricities run to meet one another, when one end touches the outside of the jar, and the other comes near the knob connected with the inside. In using the jar, it may be held in the hand, and the knob presented to the prime conductor of the machine; the inside thus acquires a positive charge, and induces a negative one on the near surface of the *outer coating* fronting it—that is, on the inside surface. The outside surface of the outer coating would then be positive; but it being in the hand, the positive electricity passes away, and leaves the outer coating entirely free for a negative charge, which it thus possesses, and thereby fixes the positive charge in the inside. The transmission of more electricity from the machine to the inner coating, induces more on the outer, till the jar is as highly charged as the strength of the excitement communicated can make it. If, now, we try the outside with a pith-ball or other electrometer, we find no sign of electricity; if we try the inside through the projecting rod, we find, indeed, a very feeble charge; but there is no appearance corresponding to the actual excitement held by the two coatings. Let us next apply the discharging-rod; and having touched the outside with one ball, let us approach the knob with the other; and while these are yet an inch or two inches apart, the two electricities will flash together with the usual spark and noise. The tension or strength of the excitement is shewn by the distance that may thus be broken through by the attraction of the opposite states for one another; just as the strength of the excitement of the prime conductor of the machine is judged of by the distance that sparks will pass through to a conductor placed near.



The strength of charge which can be communicated to a Leyden-jar depends upon the thinness of the intervening glass. The whole *quantity* of the excitement will of course be greater as the jar is larger in size; but its tension, strength, or intensity increases as the thickness of the glass is reduced. The glass offers a certain resistance to the induction, and a certain degree of tension is expended in overcoming this intermediate resistance. The particles of glass are themselves successively polarised, and it is only the surplus of the inductive power that reaches the other coating. There must, however, be a limit to the thinness of the glass of the jar. When the strength of the excitement comes up to a certain point, it forces its way through by making a hole in the glass.



In order to accumulate electricity in great quantity, a series of jars are joined together, forming a *Leyden-battery* (see preceding cut). All the insides are connected by joining their projecting knobs together, and the outsides are connected by passing wires round them from one to another, or resting them all in a continuous metallic bottom. The principle of the charge is the very same as for a single jar; and the effect is nearly what would follow from one enormous jar whose extent of coatings is equal to the sum of those which constitute the battery.

The insulating substance which separates two conducting surfaces, and enables them to sustain opposite states, is called by Faraday a *Dielectric*. All insulators are dielectrics, and the best insulators are the best dielectrics; for in as far as the dielectric is a conductor, it allows electricity to pass through in its own kind to the opposite surface, and thus discharges instead of charging the apparatus. As the glass of the Leyden-jar is not a perfect insulator, but admits a very slow conduction of electricity, the charge necessarily decays, and becomes at last extinct. With sealing-wax or shell-lac the insulation would be more perfect, and the induction better sustained.

The theory of induction furnishes an explanation of the fact that the electricity is generally unequally distributed over the surface of an excited body. In the case of a ball, the excitement is equal on all parts of the surface. But the prime conductor is generally a cylinder rounded at the ends into hemispheres, and the electricity is always stronger on the ends than on the body of the cylinder. If we take a large globe and a small one, and join them together by a rod, and pass electricity upon them, the charge will be most intense in the smallest. Whenever a surface approaches to a point or an edge, the intensity proportionally increases.

The cause is this:—We have seen that without a confronting surface to sustain an opposite charge, no body can possibly receive excitement; and the better provided a body is with a surrounding surface, the greater the charge that it can take on. Now, if we have two unequal balls on the same rod, their excitement depends upon the induction which they can exert on the surfaces about them; but the small ball being in the same room as the large, it has as good and extensive an inductive surface presented to it as the other. The two have unequal surfaces of their own; but they have the same confronting exterior surface in the walls and furniture of the room, and on this unequal proportion of surfaces depends their unequal capacity of being excited. The rounded end of a cylinder is acted on like a small ball; for a larger surface is confronted with it than with an equal portion of the body of the cylinder.

We may now understand the cause of the very great intensity of the excitement at points and edges, and the tendency that the electricity has to pass off from them. A point is a very small surface, confronted with a very large exterior, and the extent of the induced surface allows a very high intensity to be attained. This intensity favours the discharge by increasing the action upon the dielectric of air, so that the electricity will pass off from a point to an opposite body at a much greater distance than it would pass through coming from the round bulge of a large blunt cylinder. Hence, if a surface is armed with points, these will rob it of its excitement, and probably disperse it by their discharging force. The dispersion of the electricity from points is helped in another way. The intense action of points causes a current of charged air to run out from them, whose place is supplied by other air that acquires a charge in its turn, and is repelled like the previous portions. There is always a repulsion created by the passage of electricity from points, which can be made use of to create a rotatory motion, by making a sort of wheel with wire-spokes, ending in points all bent inwards in one direction, and

the whole revolving on an axis. The action is not unlike the force in Barker's mill.

When a Leyden jar or battery is discharged, the electricity may be made to travel through a long circuit, by forming a chain of conducting bodies between the inner and outer coatings of the jar. If a hundred persons, or even more, join hands, and the first touch the outside coating while the last touches the ball communicating with the inside, each will feel the shock at the same instant. The persons in the middle of the series, however, experience a less intense shock than those near the extremities; which seems to shew that the influence flows both ways, thus favouring the theory of two fluids. Electricity in its passage always chooses the best conductors, going out of the direct course to follow them. Its motion through perfect conductors is attended with no perceptible alteration in the mechanical properties of the conducting bodies, provided they be of sufficient size for the charge of the electric fluid transmitted. On the contrary, very considerable effects are produced when a powerful charge is sent through a wire which is too small to allow the whole quantity to pass with perfect freedom, or through an imperfect conductor, though of large size, as is proved when a tree is struck by lightning.

The *disruptive discharge* is the breaking or forcing of the dielectric, as when the glass of the Leyden-jar is broken through. This arises when the twist given to the particles by their electrical state is stronger than their mutual cohesion. Glass is generally able to resist such a power, but the air offers very little resistance; hence disruptive discharges readily occur in it. This discharge may be exemplified by placing a card between one of the balls of the discharging-rod and the coating of a Leyden-jar, and passing the electricity through the card: the opening which it forces can then be seen, and from it we may form some idea of the action that has taken place. The hole is very small, such as would be made by a fine needle; but it is widened on both sides, as if the force had come equally upon it from each coating. Whenever any bad conductor, such as a piece of wood, is put in the way of a discharge, it is split up or pierced in the same manner, if the charge is sufficiently powerful.

The disruptive discharge is always accompanied with a flash of light. This has various shapes, according to the conductors used. Between two good conductors of rounded or blunt surfaces—such as the ball of the discharging-rod, and the side of the jar or its knob—we have the *spark*, which is a round ball or globule of light, which passes somewhat zigzag from one to the other. This corresponds also with the most concentrated and energetic form of the discharge. The distance over which the spark will go disruptively through the air, depends upon the force of the charge, and the goodness of the conducting surfaces between which it runs. From a point, or between a good and a bad conductor, the electricity, passing off, produces a *brush* of light spreading out from a centre. When the air is rarefied, the discharge is made easier, and will pass over a greater distance. In an exhausted receiver, it will pass through two or three feet in a lambent aurora flame. By laying on a glass-plate strips of tinfoil or goldleaf, cut across and separated at every inch or short interval, and passing electricity through the whole, there will be a disruptive discharge, and a spark at every break of the continuity, and the entire metallic line on the plate will be illuminated. A great many striking effects of a similar kind can be produced in the dark from the electric light.

The concussion given to the air by the shock makes the sound that we hear, which is like the sharp crack of a whip. Both the intermediate air and the surfaces discharged are severely agitated by the sudden return from their electrified to their natural state.

There is a very perceptible sulphurous smell accompanying the discharge of electricity. The cause of it has been traced by Professor Schönbein to a peculiar substance formed during the discharge, to which he has given the name of *ozone;* and he has shewn that the same substance is produced in other ways, and has certain remarkable properties, such as the power of bleaching cotton, like chlorine.

When the discharge is interrupted by an imperfect or inadequate conductor, it tears, splits, heats, and sometimes sets fire to bodies. Very thin wires are melted; combustible substances,' such as phosphorus or gunpowder, are inflamed. The human body feels a violent stunning blow when a charge is sent through it; a very strong charge may cause irrecoverable blindness, or even instant death. A Leyden-battery of twelve jars could receive a charge sufficient to kill a man; and accidental deaths have actually occurred in working with such gigantic batteries.

ELECTRICITY OF THE ATMOSPHERE.

Franklin had the glory of discovering the identity of electricity and lightning. By putting up a kite while thunder-clouds were floating in the sky, he actually drew down by the string a distinct charge of electricity.

The electricity of the atmosphere is of the same character as frictional electricity, produced by the machine; but the source of it is a contested point. It was at one time supposed that evaporation evolved electricity, but this is now disputed, and some are of opinion that condensation of vapour has more to do with it. Heat is undoubtedly the cause more or less remotely; for electrical manifestations are more intense the warmer the climate.

The atmosphere is almost always in a state of positive excitement, and the opposite surface of the earth, consequently, negative. The intensity of the excitement undergoes regular daily fluctuations; it has two maxima or highest points, occurring (according to the observations at Kew) at ten A.M. and ten P.M.; and two minima, at two A.M. and four P.M. The intensity is also greater in winter than in summer.

Such may be considered to be the normal condition of the atmosphere. But the deposition of moisture is usually attended with disturbances and irregularities. 'In cloudy weather,' says Dr Noad, 'the free electricity of the air is still *positive.* During storms, or when it rains or snows, it is sometimes *positive*, and sometimes *negative*, and its intensity is always more considerable than in serene weather. During a storm, the electroscope will frequently indicate several changes, from *positive* to *negative.*' The electrical state of the atmosphere is examined by insulated conducting-rods, exploring-wires, and kites.

Thunder.—When a cloud becomes charged with positive or negative electricity, it produces a corresponding excitement, of the contrary kind, as well on the surface of the earth near it, as on the opposing surfaces of adjacent clouds. According to Mr Crosse, the same cloud is sometimes divided into concentric zones alternatively positive and negative. These conditions when sufficiently intense produce a thunder-storm. The clouds are seen to attract one another, and disruptive discharges take place between them. When two clouds are mutually discharged in this way, the whole commotion takes place in the upper air; the lightning is faint and diffused; and the thunder always distant. But when a large mass of positive cloud hangs over the negative earth, and when the intervening air is dry, and the accumulation great, the discharge bursts forth between the sky and the ground, and is then the most terrific and dangerous. The light has the zigzag form known by the name of forked lightning; and it is apt to be concentrated in some one spot, which is scathed and scorched by the stroke. The thunderbolts which throw down or set fire to houses, shiver trees, and destroy life, are of this character. All the effects capable of being produced on the small scale by electrical jars and batteries,

are caused on the grand scale by these thundery discharges between the clouds and the earth.

On the principle that electricity always chooses the best conductor within its reach, Franklin constructed the thunder-rod for protecting buildings. It is a rod of iron or copper, from half an inch to an inch in diameter, rising above the highest pinnacle of the building, and extending down along a wall to terminate in the ground. To receive the excitement more easily, it is pointed at the upper end, or divided into several branches, each ending in a point (see fig.). All pieces of metal on the roof should be connected with the conductor, otherwise these might attract the discharge; and they not being continued to the ground, it must pass from them to the imperfectly conducting stone and wood, and produce its destructive effects. When a house has a metallic roofing, or whether it has or not, strips of lead should be built into the walls, and connected with one another, and with all the metallic masses of the house, so that wherever lightning strikes, it may find a metallic conductor near to convey it harmless to the ground. The rod ought not to terminate in a dry conducting body, but be conveyed, if possible, to moist earth (*e*), or to a well, so that the electricity may be at once discharged into a good conducting medium.

For the protection of ships, a continuous metallic line is necessary from the mast-heads to the sea. But the conductors in this case must be suited to the changes that have to be made in the masts and rigging during the vicissitudes of a voyage; hence they are made into a chain, or formed of thin flexible strips of copper.

If a thunder-storm strike on a house that has no metallic protection, it will choose in preference bell-wires, damp walls, or gilded pictures; a human being will be preferred to dry walls or floors; hence the danger of such a visitation. But the wooden floors are better conductors than woollen cloth or feathers; hence people lying in bed in the middle of a room are likely to escape. The greatest risk is incurred when a good conductor is afforded so far, and then cut short, and an insulating substance succeeds: the lightning is thus attracted and conveyed a certain way with ease, but has then to force its passage by violence, or by going out of its course, to meet in with some tolerable conductor. The human body, from its moist state, stands high in the list of conducting substances, and would be preferred to a great many other things.

SOURCES OF ELECTRICITY.

Hitherto we have regarded friction as the source of electrical excitement; but there are many other ways of evolving it. In general, all disturbances of the molecular state of bodies, whether mechanical or chemical, are liable to produce electricity. Whatever produces heat may also be a source of electricity.

When a plate of mica is cleaved, or a roll of sulphur broken or pounded in the dark, a feeble phosphorescent light is seen. When two unlike surfaces are *pressed* together, and then quickly separated, they are in general found to be in opposite electrical states; but if one of them is a good conductor, the two electricities run together again during the separation. It has been observed that tourmaline, which shews no excitement while its temperature is stationary, becomes electric in the act of heating or of cooling, one of its poles shewing positive electricity, the other negative. The production of electricity by heat constitutes a separate branch of the subject—namely, Thermo-electricity.

VOLTAIC ELECTRICITY, OR GALVANISM.

About the end of last century, an Italian, named Galvani, discovered that by arranging two rods of different metals so that they touched one another at one end, and included between their other ends the leg of a recently killed frog, a convulsive contraction of the limb was produced. It is necessary that one of the metals should touch the nerve, and the other the muscles, in order to produce the effect. The action thus caused by the contact of two metals, or by a triangular circuit formed of two metals and a frog's leg, was found to be the very same as a shock of electricity from the common machine. A new source of electricity, independent altogether of friction, was consequently brought to light. Volta, who followed up the experiments of Galvani, was the first to construct an apparatus for obtaining the excitement in this new principle; hence the kind of electricity so produced is now called *voltaic electricity*, or *galvanism*.

Although the electricity of Volta is undoubtedly the same natural agency as the electricity of the common machine, it has, nevertheless, some characteristics that distinguish it from machine-electricity, besides its peculiar mode of development. It is found to be of feeble *strength* or *intensity*—that is to say, it can never be excited to such a stretch as to inflict the severe blows upon animate or inanimate things that the other can give. The most powerful voltaic machine that has ever been constructed could not strike a man dead, or shatter a resisting obstacle. On the other hand, the voltaic electricity can be produced in much greater *quantity* or amount than we can obtain from friction. The distinction between *intensity* and *quantity*, which is of great importance in reference to the whole of the present subject, may be familiarly illustrated by the case of heat. The *intensity* of heat is its temperature; the *quantity* depends partly on the temperature, but chiefly on the extent of the heated substance. A red-hot poker is of a very high temperature or intensity; but it does not contain so great an amount of warmth as the water of a single hot bath. The electricity of friction may be compared to a red-hot iron, that of Volta to a vast volume of warm water. Now, there are certain purposes that are best served by the high intensity; and others that require merely a great quantity, no matter how feeble the intensity. The chemical and magnetical effects of electricity are dependent on quantity alone; hence these were not produced in a very high degree till after the discoveries of Volta.

The term *current electricity* has also been given to the present branch of the subject, because the excitement arises in a constant stream, and can hardly be said to exist if it is not continually evolved. A Leyden-jar may be charged, and may remain in that state, without requiring a continual supply to be poured into it; hence the common electricity has been called *statical*, or reposing electricity, or electricity in equilibrium. But the other kind must be kept in constant motion, in order to appear at all. The voltaic machine must always be formed into a circle of conductors, where the electricity may flow round and round without interruption; in which case it is produced without ceasing.

It was supposed by Volta that the electricity arose from the simple fact of two different metals touching each other; or that there is a virtue in mere contact similar to the active rubbing of two surfaces. A crown-piece laid on a copper penny would, according to him, evolve electricity; and the one would be positively, and the other negatively charged. But there is no sufficient reason for believing that the simple contact of two bodies, apart from all other influences, is able to disengage electricity.

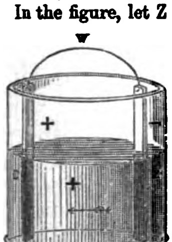
The more common belief as to the source of voltaic

electricity is, that it is due to *chemical combination*, or the union of two substances having a chemical affinity for each other. Such unions commonly produce heat in great abundance; and it can be proved that in most cases of chemical action electricity is always developed. When an acid combines with an alkali, the acid acquires positive, and the alkali negative excitement. So when an acid acts on a metal—as when zinc is plunged into oil of vitriol—the acid is positive, and the metal negative. The action of water in rusting metal would also render the metal negative.

Solutions without chemical action bring forth the electrical excitement. When alkalies are dissolved in water, they become negative, and make the water positive. When acids are mixed with one another, there is no action beyond mere solution; electricity nevertheless arises. If nitric and muriatic acid are mixed at the moment of mixture, excitement may be detected—the nitric acid being the positive ingredient.

The action of the machinery that is used for producing voltaic electricity may now be understood without much difficulty. This machinery generally consists of two metals, and a liquid capable of acting upon metallic bodies by chemical affinity. One of the metals should be acted on as strongly as possible, and the other as weakly as possible. The liquid is commonly an acid, or a corroding salt dissolved in water. Water alone will serve the purpose; but its chemical affinity for metals being faint, compared with acids, it produces feeble effects.

In the figure, let Z represent a plate of zinc immersed in a liquor capable of acting on it, and C a plate of copper; the liquid will combine with the zinc, and give it a negative electricity, and be itself positive; the copper will also be acted on, but more feebly; and hence, instead of being negative, it will receive a positive excitement from the intervening liquid, and act as a conductor to carry round the positive current.



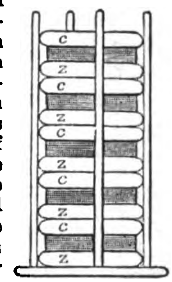
When the plates have no connection outside of the liquid, each is attacked according to the degree that it yields to the agency of the liquid; but when the circle is completed by the wire W joining the unimmersed ends of the plates, the zinc is more attacked than before, and the copper less attacked. The carrying round of the electric currents causes this effect.

The generating surface of the electricity is at the meeting of the zinc and the liquid—the *electro-motive power*, as it is called, is exerted there. From this surface the positive excitement passes through the liquid to the copper plate, and thence along the connecting-wire back to the zinc; the negative passes from the zinc along the wire in the opposite direction towards the copper. There are thus always two opposite currents of equal intensity and quantity; but it is usual in speaking of the direction of a current, to notice only the positive electricity; when an arrow indicates the direction of an electric current, it is the direction of the positive current that is meant.

Two metal plates, with a liquid between them, form a simple voltaic combination; and when the unimmersed extremities of the plates are connected, either by leaning or bending the plates themselves, or by connecting them with a wire, the circle or circuit is said to be closed. The end of the system towards which the positive current is driven, is the *positive pole*, the other end, the *negative pole*. If the connecting-wire is divided in the middle, the same names are applied to the parts connected with the two plates respectively; the extremity of the part attached to the copper plate is the positive pole, or *positive electrode*, and that of the other, the *negative electrode*.

VOLTAIC PILES AND BATTERIES.

The first form of the apparatus for evolving chemical electricity was called the *pile of Volta;* because it was constructed by Volta from a great number of round pieces of metal, like crown-pieces, piled up in a column. If a round piece of zinc is taken, and a similar piece of copper, and if a moist cloth is laid between them, a voltaic circle will be formed when an outside conductor is carried from one plate to the other. All the four elements of the circle will be present: the zinc, a corrosive liquor in contact with it, and extending to the copper, the copper, and the outside conductor from the copper to the zinc. The cloth merely serves the purpose of containing the liquid. Thus, let an upright stand be formed, with glass or wooden rods fixed into a piece of wood for a bottom. Place on the bottom a disk of zinc Z; above that a piece of woollen rag soaked with corrosive liquor, of the same size as the zinc, and upon the cloth a disk of copper. On the copper lay another piece of zinc, a wet cloth, and another piece of copper; and repeat the same process until the pile is built up to a sufficient height, being careful to observe the same order throughout. The pile will terminate in a disk of copper above, and in a disk of zinc below; and when a conducting communication, such as a piece of wire, is carried from one end to the other, a circle will be formed, and a pair of currents will be carried round and round in opposite courses, exactly as in a single circle. Commencing at the lowest zinc plate, there will be a chemical action between its surface and the liquor touching it; electricity will be developed, the negative charge will pass upon the zinc plate, and the positive will be conducted through the liquid to the first copper disk, and from it to the zinc lying upon it, and thence to the place of action between the second zinc and the second cloth, where it will be reinforced by the excitement produced at this contact, and a double charge will pass through the second cloth to the second copper, and thence to the third zinc, to be reinforced again, and pass on as before. In this way all the actions of the pieces of zinc upon their adjoining liquid will conspire into one great positive current, passing from the bottom upwards; and at the same time the negative charges arising on the zinc plates will join together in one great negative current passing downward, and going off at the lowest plate by the outside conductor, and proceeding by it to the top, to move downward again. The general course of the process will be the very same as in a single circle: the zinc end will be the negative pole, and the copper end the positive pole.

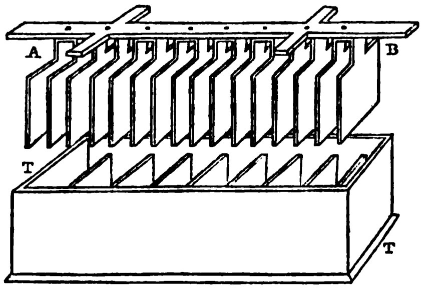


In the original arrangement of Volta there was a supernumerary plate at each end; a copper plate below the zinc at the bottom, and a zinc plate above the copper at the top. The top or positive pole was therefore called the zinc pole, and the negative pole the copper pole. The two extreme plates came afterwards to be removed as useless; and hence confusion has arisen in the designation of the poles.

The intensity of the pile increases with the number of plates. If these are few, but large, the intensity is not great, but the quantity is considerable. That is to say, such a pile would not give severe shocks, but it would have powerful magnetic and chemical effects, which, as stated, depend upon quantity, without regard to intensity.

The pieces of cloth employed in the pile being of no use but to contain the liquid, may be dispensed with, and instead of them, vessels may be used to contain both the liquid and the plates. Volta himself

made an arrangement of this sort; and all the usual forms of the voltaic battery are constructed on the principle of immersing the plates in the corroding liquor. The *trough-battery* is a procelain trough TT, divided by partitions into separate compartments or cells, each compartment being intended to receive a pair of plates



and contain the acting liquor. The plates are suspended from a piece of wood AB, at the proper distances for being immersed in the separate cells, and they are connected with one another by metallic slips; it being necessary that each plate of copper should have a conducting connection with the next plate of zinc, in order to complete the circle. No communication of any kind is allowed to take place between one cell and another: with this view the partitions are made not only water-tight, but of an insulating material like porcelain. The battery of the Royal Institution, by which Sir Humphry Davy effected the decomposition of the alkalies and earths, was of this construction, and consisted of 2000 pair of plates, with an acting surface amounting to 128,000 square inches.

THEORY OF THE VOLTAIC CIRCUIT.

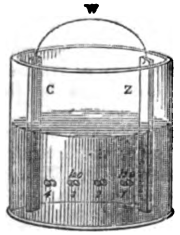
Various imperfections of a practical kind occur in the working of the piles and batteries above described, the most serious of which is, that the action, although ever so strong at first, becomes rapidly weaker and weaker, and in no very long time entirely ceases. The materials formed by the chemical action of the liquid and the zinc gradually accumulate, and stand between the fresh zinc and fresh liquor, and thus prevent the process from going on. But to remedy this and the other imperfections of the battery, it is necessary to understand clearly what the circumstances are that add to its strength, and what causes contribute to weaken and obstruct it.

Let us consider again a single pair of copper and zinc plates, immersed in a vessel containing liquid; and in the first place, let the liquid be pure water, which, though feeble in its effects, is an exciting substance. Let Z and C be the two plates, supposed to be seen edgeways, and to face one another, and connected outside by the wire W. It has been known for the last seventy years that water is not a simple, but a compound body, formed by the chemical union of two elements—oxygen and hydrogen. Each ultimate particle of water must therefore be supposed to be a compound particle, or an atom of oxygen adhering firmly to an atom of hydrogen. It is as a compound body that water acts in the voltaic circle, and as such we have to look upon it. Let the double circles 1, 2, 3, 4, stand for atoms of water, or compounds of oxygen and hydrogen; the oxygen atom being marked *o*, and the hydrogen atom *h*. An oxygen atom is supposed to be in contact with the zinc plate; and the process pursued is the following:—The zinc has, from its nature, a strong affinity for oxygen: this affinity is more powerful than the affinity of hydrogen for oxygen; and in such an arrangement as the present, the superior affinity of the zinc draws the oxygen atom to itself, dissolves the attraction between it and its hydrogen atom, sets the hydrogen free, and makes a new compound atom, called oxide of zinc. Along with this transference of the oxygen particle, there is a quantity of free electricity evolved: the oxide of zinc has a negative charge, and the disengaged hydrogen atom a positive charge. But this charge possessed by the hydrogen increases its affinity for oxygen, or makes it more powerful than a particle that has no such extra excitement. Accordingly, it approaches the oxygen end of the second particle of water, overpowers the affinity of the two atoms, combines with the oxygen, and sets the hydrogen free, charged in like manner with positive electricity. This free and charged hydrogen comes up to the third atom of water, and decomposes it in the same way; and a series of decompositions goes on till the copper plate is reached, and the action interrupted. Thus the free hydrogen appears at the copper plate, and communicates to it by contact its positive charge, rendering the copper positive, and enabling it to transmit positive electricity round the outside wire towards the zinc. The particles of free hydrogen rise up to the surface from the copper plate. The reason why the copper is not acted on in the closed circuit is, that the currents derived from the zinc overpower its own attraction for the oxygen of the water. The copper would of itself attract water-particles by their oxygen end, and decompose them; but the zinc being much more powerful in its attraction, it begins a series of decompositions that end in presenting hydrogen instead of oxygen to the copper, and in suspending its power to decompose the water. The transmission of electricity is thus effected by loosening the bonds of every compound atom that stands in its way, and by making up new combinations, where different atoms are brought together. The carrying round of the currents to the place of action quickens the energy of the combination at the surface of the zinc.

Such a circle formed out of zinc, copper, and pure water, would in a short time entirely cease, owing to the zinc becoming coated with oxide, which stands between the water and the particles of metallic zinc. But if a small portion of oil of vitriol, called also sulphuric acid, is poured into the water, it combines with and carries off the coating of oxide from the zinc plate, and leaves a clean surface; the action then goes on again with renewed energy. The acid continues to take up the oxide as fast as it is formed, and the circle is thereby rendered much more active.

When sulphuric acid combines with oxide of zinc, it forms a new substance, called sulphate of zinc, which remains dissolved through the liquid. But this new substance acquires, like the hydrogen, a positive excitement, and goes in consequence towards the copper, and is apt to form a deposit that mars the conducting power of the plate. Moreover, the hydrogen itself, by its attraction for the copper, is apt to remain stagnant on the surface, and prevent the evolution of new particles, on which the continuance of the action depends. This is remedied by pouring nitric acid into the cells, which has the power of absorbing the hydrogen as fast as it is formed at the copper; and to prevent the sulphate of zinc from going on to the copper conductor, a porous or permeable partition is interposed between the plates. This partition is called the *diaphragm*.

The power of a battery is increased by substituting for the copper a metal still less corrosive, such as silver, gold, or platinum. Platinum is, of all metals, the least acted on by acids; hence it is well adapted for the positive plate of the battery. Carbon is found even more



powerful. A further improvement is made by amalgamating the zinc plates—that is, coating them with mercury—which, from a cause not well understood, serves to diminish their waste.

Of the various forms of improved voltaic batteries, that known as *Daniell's Constant Battery* is perhaps the most effective and convenient. Each separate cell or circle consists of a cylindrical jar of copper, within which is placed another jar of unglazed porcelain, which allows the electrical excitement to pass through it. This inner jar contains diluted sulphuric acid, in which a rod of zinc is suspended; and the space between the jars is filled with a saturated solution of sulphate of copper. Here the current generated by the zinc passes through the porous diaphragm, towards the copper, while the sulphate of zinc formed by chemical action is confined. The hydrogen, again, set free at the surface of the copper cylinder, acts on the sulphate of copper in the solution, is absorbed by it, and displaces metallic copper, which is deposited on the cylinder. To renew the waste of the sulphate of copper, a few solid crystals are suspended, which dissolve gradually as they are required. Combinations of six, ten, &c., of these single cells are formed according to the power desired. The advantages of this system lie in the cheapness of the substances used and in the constancy of the action.

The strength of an electric current depends not only upon the activity of the excitement at the generating surfaces, but also upon the goodness of the conductors through which it has to pass. If the plates are far asunder, the depth of liquid between them obstructs and weakens the current. The wires also obstruct it in proportion to their length and thinness. The current passes most easily through a thick and short wire. The metals also differ greatly in their conducting power. A copper wire of 100 feet offers the same resistance as a silver wire of 136 feet, or an iron wire of 17 feet, all of equal thickness. The intensity of the electricity increases with the number of plates; hence, to transmit the current through a long circuit, a battery of many plates is used. The earth is often made to form part of the circuit, as in the electric telegraph.

EFFECTS OF VOLTAIC ELECTRICITY.

The voltaic current may produce heat, light, chemical decomposition, and mechanical power, as well as actions on the animal frame.

If a powerful pile is closed by a *thin* wire, which obstructs the passage of the current, the wire soon turns red hot. Even platinum, which cannot be fused in a furnace, yields to the voltaic pile, and iron and steel are melted and burnt. Gunpowder is now fired by this means in blasting rocks, &c.

The *light* producible by voltaic electricity is seen in the heated metals above described. A spark is also seen when the ends of the wires that close the circuit are in the act of joining or separating. But the greatest brilliancy of light is caused by making the wires end in pieces of charcoal, and bringing the pieces of charcoal together. If the pile is powerful, a brilliant stream, of an inch or more in length, may be made to pass from one point to the other. A stream of particles flows from the positive pole to the negative, leaving the end of the carbon of the former hollow, and that of the other conical.

The *chemical action* of the pile is the most important of all its effects. It was by its means that Sir Humphry Davy resolved the alkalies and earths into oxygen and a metal (see CHEMISTRY). Decomposition by this means is called *electrolysis*, and bodies which can be so decomposed are called *electrolytes*. It is only compounds of a simple kind that can be decomposed by the current; complex ones cannot. The compound must also be in the *liquid state* when the current is sent through it; ice cannot be decomposed, though water can.

When decomposition takes place, the elements always take a definite direction; oxygen goes uniformly to the positive pole, and hydrogen or a metal to the negative. Bodies that, like oxygen, go to the positive pole, are called *electro-negative*, and those that make their appearance at the other pole, *electro-positive*. The amount of decomposing force yielded by a battery is exactly equivalent to the amount of oxidation of zinc that takes place.

The *shock* of the voltaic pile differs from the discharge of a Leyden-jar; the electricity of the pile being of feeble intensity, it does not give the blow received from the jar. The greatest shock is derived from the pile of many plates. If, after moistening the hands in salt water, to heighten the conducting power of the skin, we grasp the two wires, one in each hand, a shock is felt at the first contact, and then a heating current up the arms, and a tingling sensation in the hands. A shock is also felt at the separation, arising from the sudden return of the polarised fibres of the arms to their natural state. When strong voltaic batteries are discharged through the bodies of animals recently dead, their limbs and features are convulsed and made alive in a hideous way. Experiments have been made on executed criminals, which shewed that electricity could in some degree act the part of the nervous currents in moving the bodily organs. By stimulating the nerves of the lungs, a laborious breathing was recommenced; by passing currents through the nerves of the face, the features moved and stretched themselves out into horrible grimaces; when one wire was connected with the hip and another with the heel, the leg, if bent, threw itself out with great force. In the same way, the fist could be closed, or the hand opened, by touching the proper nerves with one wire and the points of the fingers with the other. These results are only extensions of the original experiments of Galvani.

APPLICATIONS OF VOLTAIC ELECTRICITY.

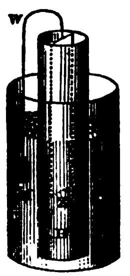
The first practical application of voltaic electricity to the arts, was the protection of the copper bottoms of ships from the destructive action of the sea-water. Sir Humphry Davy suggested that nails or wires of zinc should be fastened at intervals on the copper plates, which would cause a circuit to be formed of copper, zinc, and salt water. In this case the copper would cease to be acted on by the water, and would serve as a conducting plate to the zinc, which would be the substance wasted. Thus a small expenditure of zinc would come in place of a great expenditure of copper. A piece of zinc, equal to the head of a small nail, was found sufficient to protect between forty and fifty square inches of copper. The value of the application was, however, neutralised by a consequence which had not been foreseen. The protected copper bottom rapidly acquired a coating of sea-weeds and shell-fish, whose friction on the water became a serious resistance to the motion of the vessel, and it was discovered that the bitter poisonous taste of the copper surface, when oxidised, acted in preventing the adhesion of living objects. The principle, however, has been applied with success to protect the iron pans used in evaporating sea-water.

The greatest application of the voltaic circuit is the *Electrotype;* or the process of multiplying impressions of medals, coins, engraved plates, busts, &c., which was developed about the same time by M. Jacobi of St Petersburg and Mr Spencer of Liverpool. It is founded on what takes place in the circle of Daniell, where a solution of sulphate of copper is in contact with the copper plate, and deposits on it metallic copper. If the original plate were of a certain form, the deposited plate would exactly fit it; and if the latter could be taken off whole, its surface would be exactly the reverse of the former. If the one were a coin in relief, the other would be a coin with a hollow impression. As the copper is deposited in a shower of the finest particles, it must completely enter all the depressions and lines of the plate, and form a surface so faithfully exact in its correspondence, that no human perception could discern a

difference. The requisites of the process are, that the thing to be copied shall have a metallic surface, so that it may become the conducting plate of a circle—that something be done to prevent the coating from adhering too strongly to the original—and that the deposition should be so conducted that the deposited plate may have a close metallic texture.

The first discoverers confined themselves to the copying of metallic surfaces, such as copper-plates and coins; but a method has been found of copying plaster of Paris, wax, wood, or any non-conducting substance, by covering the surface with black-lead—a form of charcoal, which answers the purpose of a conducting plate.

The apparatus for copying a medal or coin consists of a cylindrical vessel, containing in it another cylinder of



porous porcelain to serve as a diaphragm. Thus, A is the outer cylinder; H is the diaphragm, which contains the zinc plate Z immersed in acidulated water. The outer space is filled with sulphate of copper, and in it hangs the original medal M, connected by an arching wire W with the zinc, and making a voltaic circle. The medal is covered over with wax or grease behind, and on the edges, or wherever the copper is not to be deposited. To prevent inseparable adhesion, the face is covered with a slight varnish. The action of the circle then precipitates copper on the naked surface of the medal, and goes on adding to it as long as may be desired. If the action is slow, the coating is so much the harder. To make a good impression of tolerable thickness, one or two days are allowed. If the hollow impression thus derived is put into the circle, and itself coated, a surface will be produced in relief, which will be a perfect fac-simile of the original coin. To save the double process of making first a hollow and then a relief, a cast of the original may be taken in wax or plaster of Paris, or other fusible material; this cast will then receive a surface of black-lead, or of fine copper bronze, which can be laid on with a brush. It is now a conductor, and may be inserted in the circle to receive a deposit, which will exactly resemble the original object.

To make gold or silver medals, solutions of salts of these metals must be substituted for the sulphate of copper.

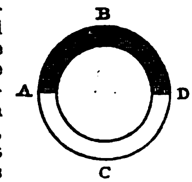
With a larger apparatus any number of copies may be made of an engraved copper-plate, and thus an unlimited supply of the finest impressions may be obtained.

Gilding and *plating* are now performed very successfully by voltaic deposition. Any metallic surface can be gilded or silver-plated, to whatever thickness may be desired. A platinum surface can also be communicated. In this way the precious metals can have their usefulness very much extended. Plants may, in like manner, be coated over with copper, and have their forms preserved for any length of time. So baskets and wickerwork can have a metallic surface communicated to them.

THERMO-ELECTRICITY.

Electricity of either kind produces heat, and heat, as we have already seen, can produce electricity. But it was only in 1832 that the means were found of producing a permanent current of electricity from heat. This discovery was made by Professor Seebeck of Berlin, and gave rise to the new science of Thermo-electricity or *heat-derived* electricity.

When two metals whose susceptibility to heat is unequal are soldered together, and heated at the joining, an electric current is evolved. Thus, if ABCD be a metallic circle, the one half, ABD, being *bismuth*, the other half *copper*, and if a lamp be applied at A, one of the joinings, it will heat both metals, and cause electric currents to flow round the circle. A positive current will pass from the bismuth to the copper, or round in the direction ACDB, the negative taking the opposite course. Thus, when two substances, differently disposed in regard to the reception of heat, are heated together at their point of contact, the discrepancy shews itself in the two metals polarising each other, and yielding electricity.



It is found that when hot water mixes with cold water, electricity is produced; the hot being negative, and the cold positive: and it appears that the passage of heat must in general cause electrical polarity. The following table exhibits the order of the principal metals in regard to thermo-electric combinations:—

Bismuth.	Platinum.	Copper.	Zinc.
Mercury.	Lead.	Silver.	Iron.
Nickel.	Tin.	Gold.	Antimony.

The further asunder two metals are in this table, the more powerful is the couple formed by them. Bismuth and iron would make the next best couple to bismuth and antimony. Each metal causes a positive current to pass upon any metal beneath it, and a negative upon any above it. The order of the metals above given does not correspond with their goodness as conductors of heat, nor exactly with any other property yet observed.

A series of bars of alternate bismuth and antimony soldered together, and then folded up in a bundle by bending, so that the first, third, fifth, &c., joinings will be at the one end of the bundle, and the second, fourth, &c., at the other, forms a compound electric circuit or thermo-electric pile. The bars are kept from touching at the sides by an insulating substance. The last rod of bismuth is connected with a wire, and forms the negative pole; and the wire attached to the last rod of antimony at the other end will be the positive pole. The two ends of the bundle are blackened to increase their absorption of heat. If either face is heated, a current will arise; if one is heated, and the other cooled, the current will be greater; if both are heated alike, there will be no current.

Such a bundle of bismuth and antimony needles has been constructed to serve as a thermometer for delicate experiments on heat. Differences of temperature, that are imperceptible by the mercury or alcohol thermometer, are found to affect the galvanometer of a thermo-electric pile. Radiant heat especially can be detected with extraordinary accuracy, by exposing one end of the bundle to the heating rays. By means of such an instrument the heat of the moon's rays has been made apparent.

MAGNETISM.

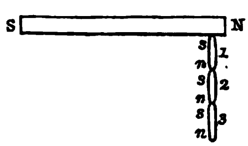
Anciently, there was found in Magnesia, in Asia, a certain kind of iron ore, in which the remarkable property was discovered of attracting other kinds of iron or steel: this ore afterwards received the name of *loadstone;* but from Magnesia, the place in which it was originally found, we derive the terms *magnet* and *magnetism.*

Besides attracting iron, the loadstone is found to have the remarkable property named *polarity;* that is to say, if a loadstone is freely suspended by a string, or lies on a pivot, it will not rest till it has settled in one position, which is a nearly north and south direction. If it be moved out of this position, it returns to it again. The term *polarity*, which has now such a wide usage in the sciences, originated in this fact. The end of the loadstone that pointed to the north pole of the earth was called its north pole, and the other end its south pole; and the loadstone was thus said to be *polar.*

But the loadstone, besides attracting iron, and pointing to the north and south poles of the earth, has the power of communicating its virtue to steel. If a bar of steel is repeatedly rubbed from end to end by a loadstone, the steel is permanently endowed with all the magnetic properties; that is, it is able to attract iron, and it arranges itself in the north and south direction. A piece of steel thus acted on is called an *artificial magnet*, the loadstone being designated the *natural magnet*. A magnet will attract iron in all its forms; but it is only iron made into steel that can take on the power of magnetising upon itself.

If we suspend a magnet till it come to rest in its north and south position, the north end is always reckoned its north pole; and this is a test for discriminating the poles. If, now, we take two magnets whose poles are known in this way, and if we present the north pole of the one to the north pole of the other, we shall find that they repel one another. But if we bring the *north* pole of the first near the *south* pole of the second, they attract each other, and cling together, end to end, and the one will draw the other after it. Hence are deduced the two general facts, or general laws of magnetic polarity—namely, *like poles repel each other; unlike poles attract each other.* We have seen that electrical attractions follow the same laws. Wherever polarity occurs—that is, whenever bodies have opposite forces residing in their opposite sides—it is on these principles that the attractions and repulsions take place.

The attraction of magnets for unmagnetised iron arises from a temporary communication of magnetism, called *induction*. This action is best understood by taking a few short pieces of iron wire and suspending one of them to a pole of the magnet. By this suspension it is made a magnet for the time, and two active poles are developed in it. If the north pole of the magnet is used, the wire 1 will have its upper end a south pole, and its lower end a north pole, ready to attract iron, as if it were a permanent loadstone. Bring now the wire 2 into contact with the first. The active north pole of No. 1 will develop an active south pole in the upper end of No. 2, and an active north pole at its lower end; the unlike poles will attract each other, and the second will hang by the first, and will have the power of communicating the same polarity, and exercising the same attraction for a third wire. The weight of wires that can be polarised and suspended is limited by the power of the magnet.

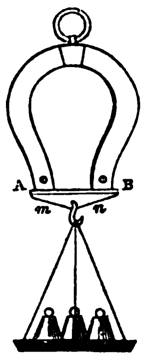


The instantaneous influence of a magnet on a bar of steel is not nearly so great as on one of soft iron; the steel resists the induction, and it requires motion and friction to magnetise it thoroughly; but when once rendered polar, steel *retains* its polarity.

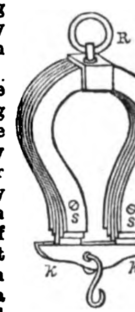
There are only a few substances capable of acquiring magnetism, either permanently or temporarily; these are the nine metals, iron, nickel, cobalt, manganese, titanium, cerium, palladium, and platinum, together with oxygen.

If a rod of copper is suspended horizontally between the poles of a horseshoe-magnet, it is repelled by both poles alike, and assumes a cross or equatorial position. This curious property, discovered by Faraday, and called *diamagnetism*, or cross-magnetism, is decidedly marked in the metals antimony, bismuth, copper, gold, lead, mercury, silver, tin, zinc; but it also belongs to almost all non-magnetic substances, solid, liquid, or gaseous.

A straight bar of steel, magnetised by rubbing, is called a bar-magnet. But it is more convenient to give magnets the form of a horseshoe, which brings their poles near each other, and makes it easy to complete the circle, and to bring both poles into play upon the same object. Such a magnet is represented in the following figure. A and B are the two poles; they are joined by the bar *mn*, which is of course polarised; *m* having the opposite magnetism from A, and *n* from B. Each horseshoe-magnet is permanently furnished with such a cross-piece, made of soft iron, which is called the *keeper*, and sometimes the *lifter*, and also the *armature*. When the magnet is used to suspend weights, these are attached to the keeper, as shewn in the figure.



In order to make a very powerful magnet, a number of single bars are joined together. This makes a *compound magnet*, or a magnetic bundle or battery. They may be either straight or horseshoe bars. A compound horseshoe-magnet is represented beneath: R is the ring for suspending it, and *kk'* the armature; the bars are magnetised before being joined, and they are fastened by screws *s* and *s* running through them.



The strength of a magnet may be gradually heightened by hanging weights to it, which are to be increased at intervals of time by little and little. On the other hand, the magnet is weakened by abruptly breaking the contact, as in drawing off the keeper suddenly. If an iron bar is in inductive contact with a magnet, and in that position receives a succession of blows with a hammer, it will acquire a fixed magnetism: so, if it is placed under induction while hot, and allowed to cool, the magnetic state will be confirmed so as to remain; also if iron, while under induction, becomes rusty, the chemical action will have the same effect in fixing the magnetism. On the other hand, a magnet when heated to redness, and then cooled, loses its magnetism entirely, as well as its steel temper.

Magnetism of the Earth.—The earth, taken as a whole, forms a great magnet, having two poles, termed its *north and south magnetic poles.* This is the cause that a magnetic bar or needle, when suspended, assumes a position nearly north and south. The exact direction of the needle at any place is the *magnetic meridian*, and the angle it makes with the true meridian, is the *declination* of the needle. This declination, or *variation* of the needle, as it is also called, is sometimes east, and sometimes west. It varies in different places, and for any one place it is generally undergoing a steady and progressive change. At Paris, for instance, in 1580, when observations first began to be recorded, the declination was 11° 30′ east; from which time it gradually decreased till 1669, when it was 0°—that is, the needle pointed due north. In 1700, it was 8° west, and went on increasing till, in 1814, it reached the maximum of 22° 34′; since then, it has been gradually diminishing, being, in 1835, 22° 4′. The present declination in England is about 24°; but it has been diminishing since 1815. The average declination for Europe is 17°, it being less as we go eastward; at St Petersburg, it is 6°; Iceland, 38°; Greenland, 50°.

It is evident how important it is for navigation that these changes of declination at different places on the ocean should be accurately known and marked on the charts. Lines drawn through all places that have the same declination are called *isogonic* lines—that is, lines of equal angles. There are two lines on the earth's

surface, one in America, the other in Asia, on which there is no declination; they run nearly north and south, but do not follow the course of meridians. They are slowly changing place, the Asiatic one advancing towards Europe.

Besides this general movement in one direction, the needle shews other variations: it has a small daily vibration, called the *diurnal variation*. From sunrise it begins its westerly sweep, which continues till about five P.M.; it then retrogrades, and continues to move east until it has reached its mean position, where it settles through the night.

If a bar or needle is made to balance itself level or evenly on an axis before being magnetised, it will not lie even, if placed in the magnetic meridian, after it has been rendered a magnet. It points downward, or is said to *dip*. This dip or *inclination* of the needle is so great in some places as to make it stand nearly upright. But the dip varies with the latitude. Near the equator, the needle is nearly level; in the regions about the north and south poles, it approaches the upright position. In this country, it inclines or dips about 70°. Captain Ross came to a place in 70° 5′ north latitude and 263° 14′ east longitude, where the needle stood perfectly upright, shewing that the north magnetic pole was directly under that spot, being thus at a considerable distance from the north pole of the earth. On the other hand, there are places in the tropics where the needle has no inclination; and every such place is said to be in the *magnetic equator*, which is formed by drawing a line through all the points where this perfect level occurs. The magnetic equator does not coincide with the earth's equator, but deviates to each side of it, and forms on the whole a very irregular line. The level of the needle is evidently produced by the equal and opposing actions of the north and south poles. North of the magnetic equator, the dip is north, and south of the equator it is south.

There is the same constant fluctuation in the inclination as in the declination of the needle. The inclination has been gradually diminishing in London for the last century. It also has daily variations. The aurora borealis has always an effect upon the magnetic needle, both in its declination and its inclination. Earthquakes and volcanic eruptions are accompanied with magnetic disturbances, which sometimes cause a permanent alteration of the needle. There occur, besides, agitations, called magnetic storms, which sometimes affect a whole continent simultaneously, and produce large vibrations in all the magnetic instruments. From all these circumstances, it appears that the earth's magnetism is undergoing incessant fluctuations and changes, some gradual and steady, others sudden and momentary.

Besides the inclination and declination caused by the earth's magnetic polarity, the *intensity* of the action has been made a matter of observation. This is measured by a separate instrument, and it is found to be least on the magnetic equator, and to increase gradually towards the magnetic poles; but, like the other two elements, it is continually varying in the same place.

In regard to inducing magnetism upon iron, the earth acts like an ordinary magnet. A bar of iron, pointed to the pole like a dipping-needle, and hammered, or cooled, or rusted in that position, becomes a magnet. So certain is this effect, that hardly any iron is ever found free from magnetism. The earth's inductive effect is rendered permanent in pieces of iron by the various modes of working and employing them, as well as by the spontaneous oxidation which occurs when they are lying unused. In high north latitudes, pokers and bars that usually stand on end inevitably acquire a small degree of magnetism. In the tropics, bars which lie on the ground nearly north and south are affected in a similar way.

The Mariner's Compass.—In using a magnetic needle as a mariner's compass (see MARITIME CONVEYANCE), to guide navigation in the open ocean, which is one of the most important applications of magnetism, a difficulty arises from the action of the iron used in building the ship upon the needle, more especially in ships altogether composed of iron. The deviations thus caused are corrected by so disposing masses of soft iron and magnetic bars near the compass, as to counteract the effect of the more distant mass of the ship. If it were merely as soft iron that the metal of the ship acted, these corrections would be less difficult; but through the inductive influence of the earth, as above explained, the iron becomes permanently magnetic, and this induced magnetism is liable to be altered by concussions and strains, according to the position of the vessel with respect to the magnetic meridian. The action of the compass thus becomes, without warning, sometimes seriously deranged, and leads to danger and shipwreck. Recent experiments seem to lead to the conclusion, that the most effectual protection for the compass, from these derangements, is to place it at a considerable elevation above the deck.

ELECTRO-MAGNETISM.

This branch of electricity was created in 1820, when Professor Oersted of Copenhagen discovered that a voltaic current has the power of magnetising an iron bar, so as to give to it all the properties of the loadstone. This discovery, taken along with thermo-electricity, completes the proof of the identity of the various natural agencies known by the names of chemical affinity, heat, electricity, and magnetism. All these influences are nothing more than modifications of one grand power pervading material bodies, and most probably derived from the sun. It is not necessary that they should be supplied separately to the earth; for out of any one of them all the others can be produced.

It had long been observed that electricity was capable of producing magnetic effects. The needles of ships' compasses, when struck with lightning, always underwent a change in their magnetic character: on some occasions their poles have been reversed, what was the north before becoming the south. Disturbances of needles have also been caused by shocks from Leyden-batteries. It was thus generally supposed that an intimate connection of some kind subsisted between electricity and magnetism. The discovery of the real nature of this connection was reserved for Oersted.

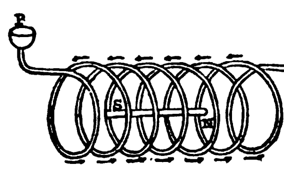
If a magnetic needle is held along the conducting-wire of a voltaic circle in action, it is made to deviate: if it is suspended along and *above* the wire, it instantly turns about and hangs directly across it: if it is next hung along and *beneath* the wire, it will deviate and lie across, but the ends will be the reverse of the former case—the end that went to one side of the wire is now on the other side: if the needle is hung along the wire *at one side*, or in the same horizontal plane, it dips; one end falling beneath the level of the conducting-wire, the other rising above it: if carried to the *other side* of the wire (without being reversed), it dips in the same way, but the pole that was down is now up. Thus it appears that a voltaic current has the power of acting on a needle; but that this power lies not in the direction of the wire, but *across it*. It is as if a magnetic power encompassed or circulated round the channel where electricity flows; or as if a particle, in receiving and transmitting the electrical polarity, acquired also a pair of magnetic poles and a magnetic axis, lying directly across the electric axis.

The connection between positive and negative currents, and north and south poles, is somewhat puzzling to remember. It may be stated thus: If a positive current passes along a wire before the breast from right to left, the head would represent the north pole of the attracted needle, and the feet the south pole; if the current flows in the opposite direction, the poles are reversed.

If the wire of an electric circuit is thus a magnet, it ought to shew attractions and repulsions for other electric wires. This actually takes place. If the wires of two circuits are laid alongside of each other, and are free to move, they are mutually repelled, if the direction of the current is the same in both, and attracted, if the currents are contrary; so that without the mediation of a steel-magnet, the forces circulating round the wires are able to shew themselves.

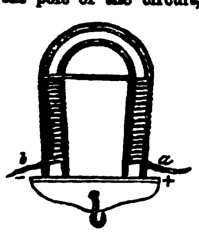
A needle of soft iron, laid across a conducting-wire, lies in the wire's magnetic direction, and is magnetised by induction. But the action of a single straight wire upon an iron rod would be very feeble. If, however, we bend the wire round the rod, and coil it again and again, we increase the amount of the magnetic circles which act on the iron. Instead of an inch of wire communicating its influence, we may have the inductive force of many feet, and a very powerful magnetism will be imparted. It is by coiled wires, therefore, that electro-magnets are formed. A spiral coil is technically called a *helix*. Such a form possesses all the powers and properties of a magnetic bar when the electric current passes through it. It attracts and repels other magnets, communicates temporary magnetism to soft iron by induction, and permanently magnetises steel.

A striking effect of the attraction of a magnetic bar by a helix is shewn in the figure, which represents a coil ending in two little cups P and *p*, where the communications



are made with the poles of the battery; a small portion of mercury is poured into each cup, and the battery-wires are dipped in the mercury, which thus forms a very perfect metallic junction. If a magnet SN is laid in the coil, and the circle completed, the action is such that the magnet starts up and suspends itself in air in the centre of the hollow, and hangs there as long as the electricity circulates. The opposing actions of the different ends and sides of the wire so neutralise each other, that it is not drawn either out or in, or nearer to one side than to another; and its only position of rest is a nearly central station: its own weight necessarily adds to the downward tendency, and keeps it a little below the axis of the spiral.

In communicating temporary magnetism to a soft iron bar, with the view of forming the electro-magnet, we may choose either a straight bar or a horseshoe: the latter is represented in the figure. The wire *a* from one pole of the circuit, is coiled round and round the iron many times, and goes off at *b* to join the other pole. If the positive current pass in at *a*, *a* will be the north pole of the magnet, and *b* the south, according to the rule already laid down. To make a powerful magnet, the copper wire should be thick, and covered with silk, to prevent the electricity from passing sideways from one coil to another, or to the iron bar. A lifter is attached for the suspension of weights. An electro-magnet may be made of far greater power than an ordinary magnet of the same size. A horseshoe whose arms are eighteen inches long, and two inches thick, may be made to sustain 1000 pounds if a strong current is passed through it.



An electro-magnet loses its polarity the instant the voltaic current ceases to flow; but if a steel needle is laid inside of a helix, and a strong current passed along, it will acquire permanent magnetism.

The *galvanometer*, or voltaic electrometer, is formed on the principle of making the current whose strength is to be measured flow parallel to the direction of a magnetic needle, and observing how far it deflects the needle from its position.

Cause of the Earth's Magnetism.—On the principle explained under the head of Thermo-electricity, electric currents will be excited at that part of the earth's surface where the sun's rays are most powerful for the instant, and will circulate round the earth from east to west. The globe is therefore in the circumstances of a coil round which an electric current is flowing, and must manifest magnetism in the direction of its axis. It is thus a great electro-magnet.

ELECTRO-MAGNETIC MACHINES.

If an electro-magnet is so arranged that when not active the lifter rests a short distance apart from the ends of the horseshoe, when the current is made to pass, the lifter is drawn up with a force depending upon the power of the magnet, which may amount to tons. On again breaking the circuit, the lifter falls away, to be again attracted on re-establishing the current. It is obvious that this alternate rise and fall of the lifter may be made a moving power in mechanics, similar to the piston of a steam-engine. Accordingly, electro-motive power is sometimes employed to give motion to machines, as in the workshops of M. Froment, the mathematical instrument-maker in Paris.

Electric Telegraph.—But by far the most important application of voltaic electricity is the electric telegraph, invented by Wheatstone, and perfected by him and others. The electric telegraph, in its various forms, depends upon the power of the voltaic current of being conveyed to a great distance, and there producing effects which can be so regulated as to compose a set of signals, or a conventional alphabet. The electricity is generated in a trough-battery adapted for the purpose. The current passes from one end of the battery along a line of conducting-wire suspended on poles, to the place to be communicated with. On the first introduction of the telegraph, a return-wire was used to complete the circuit; but it is now found that the earth can form the returning part of the circuit, so that a single line of wire suffices. At each end, the wire is carried down to the ground, and attached to a large plate of metal buried there, and the current passes through the moist earth from plate to plate. The wire is of iron, galvanised, or coated with zinc; it rests on the poles in glass or earthenware tubes, to insulate the passing electricity.

Both the magnetic and chemical effects of the current have been made use of as telegraphic signs, but chiefly the former, so that the telegraph may be considered an electro-magnetic machine.

We have seen that when a current passes over a magnetic needle, it deflects it from its position of rest—the deflection being to the right or left, according to the direction of the current. Now, by breaking and renewing the contact of the wires, the current can be set on and interrupted at pleasure; and by changing the ends of the battery with which the wires are connected (through a contrivance called a *reotrope*, or commutator), the current may be instantly reversed. Thus, a person in London, by simply swaying a handle to right or left, may cause a needle in Edinburgh to move to right or left. It may then be agreed upon that a deflection to the right shall signify the letter A; one to the left, B; two motions to the right in close succession may mean C; and so on for any number of repetitions. It is found convenient to have two or more needles, each with its own wire; and by combining their motions, an alphabet is made out without too many repetitions. This is the nature of the *needle-system* of signs generally employed in England.

Morse's system, used in the United States and

elsewhere, depends on the power of the electric current to render soft iron a temporary magnet. Such a magnet is made to act on a lever, that regulates the motion of a pencil, under which a slip of paper travels with a regulated velocity guided by clock-work. When the current is set on, the pencil presses on the paper; when it is interrupted, the pencil is raised. It is evident that a succession of dots, lines, and intervening blank spaces, of any length, may thus be formed at pleasure; and these can be interpreted according to the conventional meaning attached to them.

In the *electro-chemical* telegraph of Mr Bain, a metallic point is made to travel on a sheet of paper moistened with a chemical solution. When contact is made, the current passes from the point through the moist paper to the metal plate on which it lies, and in passing decomposes the chemical solution, leaving a coloured spot. If the current is maintained, a line is traced; and thus dots, lines, and blanks may be produced in coloured ink, as it were. With this system, according to Dr Lardner, 20,000 words can be sent 1000 miles in an hour.

The galvanic principle has also been applied to the movement and regulation of clocks. (See HOROLOGY.)

MAGNETO-ELECTRICITY.

Magneto-electricity is the counterpart of electro-magnetism: the one explains the production of magnetism by an electric current; the other shews how an electric current may be produced from a magnet. This branch of the science was created by Professor Faraday.

Since a helix charged with a current can magnetise a bar lying in it, if we take a bar-magnet and put it into a coil which has no connection with a voltaic circuit, we should naturally expect an electrical current; but no current is observed. Let us, however, seize hold of the magnet, and instead of its lying at rest in the hollow of the coil, let it be moved backwards or forwards; a current is immediately produced, the needle of the electrometer being sensibly deflected. The electricity arising from this action is called Magneto-electricity.

If an active wire, in connection with a circuit, lies alongside of another wire that is inactive and connected with a galvanometer, the current of the first has no influence in making a current in the second while both wires are at rest; but at the instant the current is arrested, and the instant that it is set on upon the first wire, a momentary current appears on the second. While the current continues, there is no action. Let, however, the wires be made to approach each other, and a current ensues on the inactive wire; when the wires are at a stand-still, it ceases. Or if they are drawn away from each other, a current in like manner arises, but opposite to the current during the approach: so that there are two methods of passing a current from an active to an inactive circle. We may either close or break the active circle, and thereby create an instantaneous current; or we may move the wires nearer or further from each other, and during either motion we have a current on the inactive circle; the approach making it in one direction, the recession making it in the opposite direction. These effects are designated by the term Volta-electric Induction; and the currents, Induction Currents.

The approximation or separation of the wires is exactly similar to the moving of the magnet in the coil, or across a wire. An active wire is a magnet, and if it is moved sideways towards another wire, the effect is the same as if a magnetic bar were moved endways. The side motion of the one, can do exactly what the longitudinal motion of the other can do. In both cases, mere proximity has no effect; but, by movement, each can excite a current in a dead circle.

By making a plate of copper revolve with its edge between the poles of a magnet, Faraday was able to produce a permanent electric current. The shock given by an induced magneto-electric current is more severe than that of a primary current. Magneto-electric machines for medical purposes are contrived so as to give the current a character of rapid intermission, which increases its effect.

ELECTRICITY OF ANIMALS AND VEGETABLES.

The most striking case of electricity produced by animals, is that of certain fishes, of which the *Torpedo* and *Gymnotus Electricus*, or electrical eel, are the most remarkable. These animals have special organs, of a large size, consisting of a number of cells, in which the electricity is generated as in a galvanic pile, but by what particular action is not understood. The upper side of the torpedo is positive, and the under negative, and the discharge is sent from the one to the other through the surrounding water, and whatever conductor intervenes. The discharge seems under the control of the will, and the animal by repeated shocks can stun its enemies and its prey.

But apart from the possession of special organs, the vital functions generally seem to be attended by the development of electricity. It has been proved by Matteucci and others, that both in living animals and in those recently killed, there is always a current circulating from the interior of a muscle to its surface. In this way, by placing a number of half thighs of frogs one upon another, is formed a *muscular pile*, capable of producing sensible effects. The surface of the human body is generally in a positive condition; but fatigue, exhaustion, and cold are said to produce a negative condition.

The effects of a voltaic current sent through the nerves are remarkable. It produces contractions of the muscles, and convulsive motions of the limbs. The bodies of men and animals recently deprived of life, are thus thrown into a state of violent activity resembling life. Suspended animation has thus occasionally been restored. When the current traverses any part of the optic nerve, a sensation of light is produced; similarly, the effect on the nerves of hearing is to excite the sensation of sound; and so with the other senses.

If a current continue to pass along a motor nerve for some time, the nerve loses its excitability; but this is restored by reversing the current. The chief effect is always produced at the beginning and end of the contact. From these and similar facts, it was not unnatural to suppose that the nerve-force, or nervous energy, may be nothing else than an electric current. Careful examination, however, disproves this; no indications of an electrical current can be detected in the nerves of living animals, nor indeed does the arrangement seem to admit of it, there being no appearance of a closed circuit. But though not identical, the two forces are analogous, and intimately related, similarly to heat and electricity. 'The development of electricity by a crystal of tourmaline when heated, clearly proves the relation between heat and electricity: a similar relation between the nervous force and electricity is demonstrated by electric fishes. Electricity is not, however, the nervous force, any more than *heat* is electricity: the one changes into the other in the one case, by the form of the integrant molecules of the crystal; and in the other, by the structure of the electric organs.'

Recent researches would seem to establish the fact, that the process of vegetation also excites abundance of electricity. Currents are said to be detected in all parts of vegetables. The result of one set of experiments is, that 'the roots and all the interior parts of the plants filled with sap, are permanently *negative*, while the moist surfaces of the fresh branches, leaves, &c., are permanently *positive*.' It is not unlikely that vegetation thus exercises a powerful influence on the electrical condition of the atmosphere.

CHRONOLOGY—HOROLOGY.

THE general relation of events and successive existences to each other we denominate *Time*—a thing of duration, involving the past, the present, and the future. It is evident that for the measurement of time we can have no standard of the same tangible nature with a pound, a yard, or a pint measure. We must have recourse to the space or duration involved in some continued or reiterated *motion*, as to which we have all the proof possible in the nature of the thing, that it requires the same period for its recurrence on one occasion as on every other. The motions of the heavenly bodies are of such a nature, and present the surest standard of reckoning time on a large and comprehensive scale. For periods, however, less in duration than a single day, or day and night, there are no explicit natural standards; hence the utility and necessity of mechanism of human invention, the motions of which, mathematically adjusted and numbered, shall measure and record more brief and arbitrary divisions.

In accordance, therefore, with what is the common practice of mankind in applying such a scale of time to the general routine and business of life, especially in its more civilised condition, we purpose to treat—*first*, of the measurement of time by days, months, years, and cycles, considered with special reference to their respective natural and artificial subdivisions and accumulations; and, *secondly*, of those instruments and machines which have been invented for dividing the leading astronomical unit, or day, into seconds, minutes, and hours. The former of these departments may be termed *Chronology*, or the science of time in general; the latter, *Horology*, or an explanation of the various contrivances which have been devised for marking and measuring its arbitrary subdivisions.

CHRONOLOGY.

Chronology—from *chronos*, time, and *logos*, discourse—is literally the doctrine of time; the science which treats of its various divisions, and of the order and succession of events. The chronologist has thus a threefold duty to perform—namely, to assign a measure to the interval which elapses between the recurrence of any natural event; to determine certain points or epochs from which to date occurrences, whether preceding or succeeding that epoch; and, lastly, dating from any given epoch, to arrange in due order all facts and phenomena which may be considered of importance. Adopting this course, we shall treat, in the first place, of the division of time into

DAYS AND HOURS.

The day is that portion of time which elapses while the earth turns once completely round on its axis—one half of its surface being exposed, alternately, to the light of the sun on the one hand, and to the darkness of the starry heavens on the other—thus producing to those carried round with it the succession of day and night, and the apparent phenomenon of a diurnal revolution of the sun from one point in the illuminated atmosphere back again to the same point, or nearly so, as explained under ASTRONOMY.

The succession of day and night would undoubtedly constitute the first great natural period reckoned by the human race—involving, as it does, not only the most familiar and most strikingly contrasted phenomena within the bounds of man's experience, but phenomena peculiarly adapted to the great necessities of his nature—those of vigilance and sleep. Yet the precise point at which the day should be held to begin and terminate, must have been a matter much less easily settled; and accordingly we find, that while amongst ancient nations—the Babylonians, Persians, Syrians, Greeks, and almost all the nations of Asia—the day began at sunrise, and was held to last throughout the whole of the ensuing daylight and darkness—an arrangement better adapted to countries near the tropics than elsewhere, as the sun there rises more nearly about the same time throughout the year—the Jews, Turks, Austrians, and others, with some of the Italians and Germans, have begun their day about sunset; the Arabians theirs at noon, as do astronomers and navigators of all nations; the ancient Egyptians, and most of the modern Europeans and Americans, on the other hand, as well as the modern Chinese, beginning theirs at midnight, which is evidently the most convenient method, since it throws all the waking and active portion of the day under one date.

The subdivision of the day into morning, forenoon, mid-day, afternoon, evening, and night, is natural, though somewhat indefinite, and may be conceived to have always been more or less marked by man, even in his rudest state. At all events, the ancient Chaldeans, Syrians, Persians, Indians, Jews, and Romans, divided the day and the night into four parts; but there is nothing obvious in the natural changes or motions of the sun, moon, earth, or stars, which could point out the division of days into hours, hours into minutes, or minutes into seconds. These divisions are entirely artificial and arbitrary, unless, indeed, we conceive the second to represent that minutest portion of time which, to the human mind, constitutes its natural unit or rudiment, as particles constitute the units of a mass; but even seconds have been subdivided into thirds; and still it is evident that, after all, these are no more the minutest elements of time than are molecules the minutest elements of masses.

In the civilised part of the world, it is now customary to divide the day, and reckon the minuter portions of time, by instruments to be afterwards described, in seconds, sixty of which constitute a minute; in minutes, sixty of which constitute an hour; and in hours, twenty-four of which constitute a day. Most nations have these instruments marked for only twelve hours, the computation being twofold, like the day itself; but the Italians, Bohemians, and Poles, run them on from the first to the twenty-fourth—from one o'clock to twenty-four o'clock. The Chinese, on the other hand, divide the day into twelve hours only, each being, therefore, twice the length of ours. When the decimal system was adopted by the French, the day was necessarily divided into ten hours.

The length of time which elapses while any given point on the earth's surface passes from its corresponding point in the starry firmament, and returns to the same point, is called the *sidereal* day, and is found, when measured by the motions of the ordinary instruments invented for the purpose of pointing out its subdivisions—namely, time-keepers—to consist of, or be equal to, 23 hours 56 minutes 3 seconds, and (to be still more exact, as astronomers require to be) 4 thirds—a third being the sixtieth part of a second. But although the distance of any fixed star in the firmament is so immense, that the whole orbit of the earth is but, as it were, a point itself in comparison, and the motion of the earth in that orbit, therefore, cannot alter or affect the length of the sidereal day to any appreciable extent, it is otherwise

with the *solar* or natural day, which is that portion of time elapsing between the arrival of the sun at the meridian, or mid-day, on two consecutive days. The mean length of this period of time is twenty-four hours; nearly 3 minutes 56 seconds on the average being required, in consequence of the earth's motion in its orbit, to bring the sun up to the same meridian on every successive day. The inclination of the plane of the earth's equator to the plane of its orbit, however, and the unequal rapidity of the motion of the earth in its orbit, really cause the solar or natural days to be of unequal length; so that, though averaging twenty-four hours each, they sometimes fall short, and sometimes exceed that average. (See ASTRONOMY.)

We have thus three species of day—the sidereal, or that time which elapses between two successive culminations of the same star, and which is now universally adopted by astronomers in their observatories; the solar, natural, or apparent day, being the time that elapses between two consecutive returns of the same terrestrial meridian to the centre of the sun, and which consequently commences at noon; and the civil or mean solar day, which is the mean or average of these meridional returns, and which most modern nations have adopted, placing the commencement and termination at mean midnight.

It is here necessary to observe, that as the earth rotates from west to east, every meridian has its own natural day; and any place east or west of that meridian has a corresponding earlier or later sunrise. The earth, of 360° of longitude, turns in twenty-four hours; consequently every hour is equal to 15°; and every degree equal to four minutes of time. Thus, taking Greenwich as the normal meridian, Alexandria being 30° east, is two hours earlier, or has it twelve o'clock when it is ten at Greenwich; Bengal is 90° east, and it is there twelve at noon when only six in the morning at Greenwich. So New York is 74° west, or 4 hours 56 minutes; and consequently, when noon at Greenwich, it is only four minutes past seven in the morning at New York. As with these large distances, so with every other difference of longitude, however minute; and it is thus that we speak of our clocks being earlier or later than Greenwich time, according as we are situated east or west of that meridian. Ipswich, for example, being east of Greenwich, is about five minutes before, or earlier; Edinburgh, being west, is about twelve and a half minutes behind; and Dublin, being still further west, is about twenty-five minutes late. Hence the necessity, in these days of rapid transit, of keeping by one uniform standard of time, or at least of having a table of differences for the principal stations throughout the country. In most cases, it would be preferable to have our clocks furnished with two minute-hands—one to indicate Greenwich time, and the other the natural time of the locality.

MONTHS AND WEEKS.

After the day, the next distinct natural measure or division of time marked out by the heavenly bodies in their time-keeping revolutions, is the month. The lunar month is the period during which the moon revolves once round the earth, and is equal to 29 days 12 hours 44 minutes 3 seconds. The solar month is the period during which the sun appears to pass through a twelfth part of his annual course, or through one of the twelve arbitrary signs of the zodiac, and is equal to 30 days 10 hours 30 minutes: it is not so distinctly pointed out by nature as the lunar month. The month came ultimately to be disconnected from the lunar and terrestrial revolutions, as will be afterwards more particularly noticed, and civil or calendar months, accommodated to the year, were substituted; these also, as well as the names given to them in their annual order, will fall to be noticed while treating of the year itself and its subdivisions.

The subdivision of the month into weeks of seven days is very ancient, having, from the most remote period of history, been in use among the Hindoos and other nations in the East, including the Chaldeans and Jews. The week did not enter into the calendar of the Greeks, who divided the civil month into three periods, of ten days each; and it was not introduced at Rome till the time of the Emperor Theodosius. The Roman month was anciently divided into three periods—*Calends*, *Nones*, and *Ides*. The calends were invariably placed at the beginning of the month; the ides at the middle of the month, on the 13th or 15th; and the nones (*novem*, nine) were the ninth day before the ides, counting inclusively. From these three terms the days were counted backwards in the following manner:—Those days comprised between the calends and the nones were denominated *days before the nones;* those between the nones and ides, *days before the ides;* and those from the ides to the end of the month, *days before the calends.* The Greeks had no calends; hence the Roman phrase *Græcæ calendæ*, or 'never,' corresponding to the English 'Latter Lammas,' and the Scotch 'Morn come never.'

The use of weeks is supposed by some to be a remnant of the tradition of creation; by others, as suggested by the phases of the moon; while a third class refer its origin to the seven planets known in ancient times. The latter hypothesis explains the circumstance, that the days of the week have been universally named after the planets in a particular order. Thus the French, at the present day, following the practice of the ancients, name the days from Mercury, Jupiter, Venus, &c.; while the English adopt Saxon appellations, derived from the deities of Northern Europe, and from the sun and moon. Hence our term Sunday is from the *Sun;* Monday, the *Moon;* Tuesday, *Tuesco;* Wednesday, *Woden;* Thursday, *Thor;* Friday, *Friga;* and Saturday, *Seater.* (See SUPERSTITIONS.) In England, the Latin names of the days are still retained in legislative and judiciary acts. The Quakers, or Society of Friends, do not use the name of the week-day, but call each day, as they do the months, by its proper number—reckoning Sunday the 1st, Monday the 2d; and so on.

YEARS AND SEASONS.

The year, properly so called, or the solar or astronomical year, is that portion of time which elapses while the sun passes through the twelve signs of the zodiac, or rather, while the earth revolves once completely round the sun in its orbit; and while, from the parallelism of the axis of the earth's rotation to itself, combined with its inclination to the axis of the orbit, each hemisphere is turned alternately, once toward, and once from the sun; thus constituting, at least in the extra-tropical regions, the distinction between summer and winter. (See ASTRONOMY.)

The distinction of the seasons would soon be found to depend upon the alternate approach and departure, or elevation and depression, of the sun in the heavens at stated and regularly recurring intervals; but the exact division of time into solar years could not have been effected till astronomy had made some progress; when it would immediately appear, in the endeavours at length made to measure the year by revolutions of the moon, that as an exact number of days, or times of the earth's rotation, is not contained in 'a moon,' or lunar month, so an exact number of moons, or even of days, is not contained in a year, or revolution of the seasons. Such observations as these led to methods of accommodating the one period to the other; or, in other words, to the

ADJUSTMENT OF THE CALENDAR.

The Chaldeans, Egyptians, and Indians, and indeed almost all the nations of antiquity, originally estimated the year, or the periodical return of summer and winter, by twelve lunations—a period equal to 354 days 8 hours 48 minutes 36 seconds. But the solar year is equal to 365 days 5 hours 48 minutes 49 seconds; or 10 days

21 hours 13 seconds longer than the lunar year, an excess named the *epact;* and, accordingly, the seasons were found rapidly to deviate from the particular months to which they at first corresponded; so that in thirty-four years, the summer months would have become the winter ones, had not this enormous aberration been corrected by the addition or intercalation of a few odd days at certain intervals. Thus was the calendar first adjusted, and the solar year estimated to consist of twelve months, comprehending 365 days. But no account was taken of the odd hours, until their accumulation forced them into notice; and a nearer approximation to the exact measurement of a year was made about forty-five years before the birth of Christ, when Julius Cæsar, being led by Sosigenes, an astronomer of his time, to believe the error to consist of exactly six hours in the year, ordained that these should be set aside, and accumulated for four years, when of course they would amount to a day of twenty-four hours, to be accordingly added to every fourth year. This was done by doubling or repeating the 24th of February; and, in order to commence aright, he ordained the first to be a 'year of confusion,' made up of fifteen months, so as to cover the ninety days which had been then lost. The 'Julian style' and the 'Julian era' were then commenced; and so practically useful and comparatively perfect was this mode of time-reckoning, that it prevailed generally amongst Christian nations, and remained undisturbed till the renewed accumulation of the remaining error of eleven minutes or so had amounted, in 1582 years after the birth of Christ, to ten complete days; the vernal equinox falling on the 11th instead of the 21st of March, as it did at the time of the Council of Nice, 325 years after the birth of Christ.

This shifting of days had caused great disturbances, by unfixing the times of the celebration of Easter, and hence of all the other movable feasts. And accordingly, Pope Gregory XIII., after deep study and calculation, ordained that ten days should be deducted from the year 1582, by calling what, according to the old calendar, would have been reckoned the 5th of October, the 15th of October 1582. In Spain, Portugal, and part of Italy, the pope was exactly obeyed. In France, the change took place in the same year, by calling the 10th the 20th of December. In the Low Countries, the change was from the 15th December to the 25th, but was resisted by the Protestant part of the community till the year 1700. The Catholic nations, in general, adopted the *style* ordained by their sovereign pontiff; but the Protestants were then too much inflamed against Catholicism in all its relations, to receive even a purely scientific improvement from such hands. The Lutherans of Germany, Switzerland, and, as already mentioned, of the Low Countries, at length gave way in 1700, when it had become necessary to omit *eleven* instead of ten days. A bill to this effect had been brought before the parliament of England in 1585, but does not appear to have gone beyond a second reading in the House of Lords. It was not till 1751, and after great inconvenience had been experienced for nearly two centuries, from the difference of the reckoning, that an act was passed (24 Geo. II., 1751) for equalising the style in Great Britain and Ireland with that used in other countries of Europe. It was enacted, in the first place, that eleven days should be omitted after the 2d of September 1752, so that the ensuing day should be the 14th; and, in order to counteract a certain minute overplus of time, that 'the years 1800, 1900, 2100, 2200, 2300, or any other hundredth year of our Lord which shall happen in time to come, except only every fourth hundredth year of our Lord, whereof the year 2000 shall be the first, shall not be considered as leap-years.' A similar change was about the same time made in Sweden and Tuscany; and Russia is now the only country which adheres to the *old style;* an adherence which renders it necessary, when a letter is thence addressed to a person in another country, that the date should be given thus:—April $\frac{1}{13}$ or $\frac{\text{June 26}}{\text{July 8}}$; for it will be observed, the year 1800, not being considered by us as a leap-year, has interjected another (or twelfth) day between old and new style.

The twelve calendar or civil months were so arranged by Julius Cæsar, while reforming the calendar, that the odd months—the first, third, fifth, and so on, should contain thirty-one days, and the even numbers thirty days, except in the case of February, which was to have thirty only in what has been improperly termed leap-year, while on other years it was assigned twenty-nine days only; a number which it retained till Augustus Cæsar deprived it of another day. The names of the twelve months are strictly Roman:—Thus, *January* is said to be derived from Janus, a divinity who presided over the commencement of all undertakings, whence his name was appropriately applied to the first month in the year; *February*, from *februo*, 'I purify,' because in that month funeral lustrations were performed at Rome; *March*, from Mars, the reputed father of Romulus; *April*, probably from *aperire*, 'to open,' in allusion to the opening or budding of vegetation; *May*, from Maia, the mother of Mercury, to whom sacrifices were offered on the first day; *June*, according to some, either from Junius, Juno, or Juniores; *July*, in honour of Julius Cæsar; *August*, in honour of Augustus; *September*, *October*, *November*, and *December*, signifying respectively seventh, eighth, ninth, and tenth, are the names which were employed when the Roman year consisted only of ten months, and began with March.

The commencement of the year, till a comparatively very recent period, was the subject of no general rule. The Athenians commenced it in June, the Macedonians in September, the Romans first in March, and afterwards in January, the Persians on 11th August, the Mexicans on 23d February, the Mohammedans in July, and astronomers at the vernal equinox. Amongst Christians, Christmas-day, the day of the Circumcision, the 1st of January, the day of the Conception, the 15th of March, and Easter-day, have all been used at various times, and by various nations, as the initial day of the year. Christmas-day was the ecclesiastical beginning of the year, till Pope Gregory XIII., on reforming the calendar, ordered it, in 1582, to begin thenceforward on the 1st of January. In France and England, the same practice commenced about the same time; but in the latter country, it was not till 1752 that legal writs and instruments ceased to consider the 25th of March as the beginning of the year. In Scotland, New-year's Day was altered, both for historical and legal purposes, from the 25th of March to the 1st of January, by a proclamation of King James VI., in the year 1600. The English plan was found exceedingly inconvenient; for when it was necessary to express a date between the 1st of January, which was the commencement of the historical year, and the 25th of March, which opened the legal one, error and confusion were sure to occur, unless it were given in the following awkward fashion:—January 30, 1648–9, or 164$\frac{8}{9}$. Even this was apt to lead to mistakes; and it is perhaps even to this day a matter of doubt with some intelligent persons, whether the execution of Charles I., of which the above is the usual appearance of the date, occurred in the year 1648 or 1649: it in reality occurred in the year which, by our present uniform mode of reckoning, would be called 1649.

The present mode of reckoning time has experienced no interruption in its leading features for many years, except under the French Republic. In September 1793, the French nation having resolved that the foundation of their new system of government should form their era, instead of the birth of Christ, whose religion they had in a great measure shaken off, resolved also that a calendar should be adopted on what was termed philosophical principles. The Convention, therefore, having

decreed, on the 24th November 1793, that the common era should be abolished in all civil affairs, and that the new French era should commence from the foundation of the Republic—namely, on the 22d September 1792, on the day of the true autumnal equinox—ordained that each year henceforth should begin at the midnight of the day on which the true autumnal equinox falls. This year they divided into twelve months of thirty days each, to which they gave descriptive names as follows:—From the 22d of September to the 21st of October was *Vendémiaire* (Vintage Month); to the 20th November was *Brumaire* (Foggy Month); to the 20th December was *Frimaire* (Sleety Month); this completed the autumn quarter: to the 19th January was *Nivose* (Snowy Month); to the 18th February was *Pluviose* (Rainy Month); to the 20th March was *Ventose* (Windy Month), which completed the winter quarter: to the 19th April was *Germinal* (Budding Month); to the 19th May was *Floréal* (Flowery Month); to the 18th June was *Prairial* (Pasture Month); here ended the spring quarter: to the 18th July was *Messidor* (Harvest Month); to the 17th August was *Fervidor* or *Thermidor* (Hot Month); to the 16th September was *Fructidor* (Fruit Month), which terminated the period of summer. In ordinary years there are five extra days—namely, from the 17th to the 21st of our September, inclusive: these the French called *Jours Complémentaires*, or *Sans-culottides*, and held as festivals; the first being dedicated to Virtue, the second to Genius, the third to Labour, the fourth to Opinion, and the fifth to Rewards. At the end of every four years, forming what they called a Franciade, occurred a leap-year, which gave a sixth complementary day, styled *Le Jour de la Révolution*, and employed in renewing the national oath to live free or die.

The *week*, though not exclusively a Christian or Jewish period of time, they also abjured. The thirty days of the month were divided into three parts, of ten days each, called *Décades;* of which the first nine—called Primidi, Duodi, Tridi, Quartidi, Quintidi, Sextidi, Septidi, Octidi, Nonidi—were working or common days, while the tenth, styled Décadi, was observed as a kind of Sabbath, though not exactly in the Jewish sense of the word. The French, however, in indicating any particular day, either by word or writing, generally mentioned only the number of the day of the month. The Republican Calendar was first used on the 26th of November 1793, and was discontinued on the 31st of December 1805, when the calendar used throughout the rest of Europe was resumed.

CYCLES.

A cycle, from a Greek word signifying *circle*, is a perpetual round or circulating period of time, on the completion of which, certain phenomena return in the same order; the end being thus, as it were, brought back to the beginning. Under such a definition, the common practice of accumulating years into centuries has of course no title to be classed: it is merely an arithmetical computation, like the equally common mode of counting by tens—forming, indeed, part of the same system.

The *Solar Cycle* is a period of twenty-eight years, during which the day of the month, in every succeeding year, falls on a different day of the week, from the first, till the cycle is completed; when the days of the month and week meet as at first, one cycle corresponding to another. By this cycle, which has no relation to the sun's course, we find 'the Dominical letters,' or those letters amongst the first seven in the alphabet—used to represent the days of the week—which point out the days of the month on which the Sundays fall during each year of the cycle. If there were 364 days in the year, the Sundays would happen every year on the same days of the month; if 365 exactly, every seventh year; but because the additional fractional period contained in the year makes an alteration of a day in every fourth year, the cycle extends to four times seven, or twenty-eight years.

The first solar cycle in the Christian era having begun nine years before the commencement of that era, to discover what year of the cycle the year 1856 forms, we must add 9, and divide the sum 1865 by 28, the period of the cycle, and the quotient 66 is the number of solar cycles that have passed during that era, the remaining 17 being the year of the cycle corresponding to 1856.

The *Lunar Cycle*—also called the 'Golden Number,' from its having been written in letters of gold by the Greeks, and the 'Metonic Cycle,' from its having been discovered by Meton, an Athenian astronomer—is a period of nineteen years, at the end of which the phases of the moon occur on the same days of the civil month as in a previous lunar cycle, and within an hour and a half of the same precise moment of time.

The first lunar cycle in the Christian era having begun one year before the commencement of that era, to discover what year of the cycle 1856 forms, we must add 1, and divide the sum 1857 by 19, the period of the cycle, and the quotient 97 is the number of lunar cycles that have passed during that era: the remainder, 14, shewing that 1856 is the fourteenth year of the next lunar cycle.

The *Dionysian Period* is a combination of the solar and lunar cycles, forming, by the multiplication of 28 by 19, a period of 532 years, at the expiration of which it is again new moon on the same days of the week and month as before: chronological events are compared and tested by such a calculation.

The *Indiction* may here also be noticed; though, were it not for severing it from the other cycles with which it is connected in the Julian period, it might perhaps more properly appear under the head of epochs and eras. This was a Roman period of fifteen years, the first of which commenced in the year 312 after the birth of Christ. It was appointed merely for the regulation of certain payments by the subjects of the empire; but it came to be observed by the Greek Church and the Venetian senate, as well as the court of Rome.

The *Julian Period* is a combination of the solar and lunar cycles with the Indiction; the respective periods of 28, 19, and 15 years being multiplied by each other, and the product, 7980 years, being what is called the Julian period, during which there cannot be two years having the same numbers for the three cycles; but at the termination of this period they return in the former order.

The year 1856 is the 6569th of the Julian period: hence it began about 700 years previous to the date vulgarly assigned to the creation of the world, and has been used instead of that era, to obviate the disputes of chronologers, and to reconcile their systems; for all agree as to the year in which the Julian period began.

The *Precession of the Equinoxes*, on the supposition that the motion on which it depends is uniform, is a cycle of 25,868 years, during which the points whereat the sun crosses the equator at the equinoxes retrograde along the whole circle of the ecliptic, and return to their former position. The present rate of this motion, which depends on the solar and lunar attraction of the quantity of matter heaped up along the region of the equator, is fifty seconds of a degree yearly, or a whole degree in seventy-six years. (See ASTRONOMY.)

Sir Isaac Newton endeavoured to fix the period of the Argonautic expedition by this cycle, and it has given rise to some curious and interesting speculations regarding the period when the signs of the zodiac were invented.

EPOCHS AND ERAS.

The principal difficulty which must have presented itself to nations desirous of preserving the memory of

events, as they might occur, in their annals from day to day, from month to month, and from year to year, and for long periods of years, would be to obtain a starting-point from which to number these days, months, years, and periods of years; and as no very marked astronomical event (unless, perhaps, eclipses) could render one of these starting-points preferable to another, such starting-points came practically and generally to consist, in early times, when nations had little mutual intercourse, of some event, important or known, perhaps, only to the nation dating from it. This event would form *an epoch*, so named from a Greek word signifying to stop. The enumeration and series of years computed from an epoch is called *an era;* and accordingly of epochs and eras there have been almost as many as there have been of nations. As the eras of ancient nations, however, have become obsolete, it would be useless, as it is here impossible, to enumerate all that we know of, or even any great number of them. But we shall notice a few of the most important in the meantime, reserving the names of all the other principal eras to be afterwards presented together in a tabular form.

The *Era of the Olympiads* is the first on record, and it also became the most celebrated of the ancient methods of computing lengthened periods of time. It took its rise amongst the Greeks 776 years before the birth of Christ. Public games had been instituted at Olympia, a city in Elis, which took place every fourth year, at the recurrence of the full moon after the summer solstice—namely, about the beginning of our July. As this festival made a great impression on the public mind, the people began to reckon by Olympiads, or recurrences of the Olympic games—an Olympiad comprising four years. The computation by Olympiads ceased after the 364th Olympiad, in the 440th year after the birth of Christ, as usually computed. The Greeks latterly adopted a new era, called

The *Era of Seleucus*, or the *Seleucidæ*, sometimes also called the era of Alexandria. This era commenced twelve years after the death of Alexander the Great, at the first conquest (312 B.C.), by Seleucus Nicator, of that part of the west which afterwards formed the immense empire of Syria. This era has also prevailed, and still exists, amongst the people inhabiting the Levant. The Jews reckoned by it till the fifteenth century of the Christian era, when they substituted the supposed era of the Creation, to be afterwards noticed; and they still begin their year according to it, in the months of September or October.

The *Roman Era* was reckoned by the Romans from the epoch of the foundation of their famous city Rome, an epoch taken to correspond to the 753d year before the birth of Christ. The computation of time by the Roman era ceased in the sixth century of the Christian era.

The *Christian Era*, of which we now live in the 1857th year, was not adopted as a mode of time-reckoning immediately after the commencement of Christianity. That religion existed long in a very obscure way; and the date of the birth of its founder did not, for several centuries, become a sufficiently important event in the eyes of enlightened nations to cause them to make it an era. The era of the Olympiads, the Roman era, the era of Seleucus, and the dates of ecclesiastical councils, and other events then considered of importance, were the common modes of reckoning, and continued partially to be so till a period less remote than many people suppose. Even in Italy, and its celebrated capital, Rome, which became the chief seat of Christianity at a very early period, this era was not used till the sixth century. It was introduced into France in the seventh, but not fully established till the eighth century. In Spain, though occasionally adopted in the eleventh, it was not uniformly used in public instruments till after the middle of the fourteenth century, nor in Portugal till about the year 1415. Now, however, all nations professing Christianity have abandoned other eras, and confined themselves to this; using the Latin words *Anno Domini*, 'the year of our Lord,' or their initial letters, A.D., to distinguish it; while for all dates previous to the generally received epoch of the era, the words *Anno ante Christum*, 'the year before Christ,' their abbreviation A.A.C., or more usually the letters B.C., signifying 'before Christ,' are used.

The *Era of the Hegira* commences at the epoch of the flight of Mohammed from Mecca to Medina, which took place on the 16th day of July 622 A.D. The Mohammedan year is regulated by this event; hence it is used by the Turks, Arabs, and other Mohammedans, comprising a large portion of the modern population of the world.

The *Mundane Era*, or era of the creation of the world, has been the subject of much controversy. As many as 300 different opinions, according to Kennedy, in his *Scriptural Chronology*, have been entertained regarding the period which elapsed between the creation and the incarnation. Some have made it 3616 years; others 6484. From the creation to the deluge, the computation of the Hebrew text makes a lapse of 1656 years; the Samaritan version only 1307; the Septuagint 2262. No ancient chronologist attempted to fix the epoch of the creation: some conceived it impious to do so. In modern times, the impiety has been supposed to lie all the other way. But some enlightened commentators have been bold enough to return to the ancient orthodox idea, so far at least as to maintain that the Scriptural epoch of the creation is indefinite, being merely cursorily alluded to in the words, 'In the beginning God created the heavens and the earth.' Geologists, in general, also adopt this wide interpretation. In the authorised version of the Bible, however, the chronology usually given places the epoch of the creation in the year 4004 B.C. Thus, 1 A.D. is 4004 A.M.; the letters A.M. being used as an abbreviation of *Anno Mundi*, 'year of the world.'

YEARS OF PRINCIPAL ERAS CORRESPONDENT TO 1856.

		Years.	Abbrev.
Era of Creation (Constantinopolitan account),		7364	A.M. Const.
Era of Creation (Alexandrian account),		7348	A.M. Alex.
" " (Jewish account), 23d Thebet,		5616	A.M.
Julian period,		6569	Jul. Per.
Caliyug (Hindoo),	Poos or Margaly,	4957	Cal.
Era of Abraham,	4th month of	3871	Ær. Abr.
Olympiads,	7th month 1st year of	662	Olymp.
Era of Rome,		2609	A.U.C.
Era of Nabonassar,	8th month of	2604	Ær. Nab.
Egyptian era,	25th Cohiac,	2602	A. Æg.
Era of Death of Alexander,	3d month,	2179	A. Mort. Alex.
Spanish, or era of the Cæsars,		1894	A. Cæs.
Dioclesian, or era of Martyrs,	25th Cohiac,	1572	Ær. Diocl.
Hegira,	22d Rabiu II.	1272	A.H.
Chinese year,	53d year of 71st cycle of 60 years.		

MISCELLANEOUS PERIODS.

Besides these major periods, we have others of less significance, but still useful to be known, as they are frequently alluded to in works of a historical nature. Thus, a *lustre* (Lat. *lustrum*) is a period of five years; or, more properly, the completion of fifty months, at the end of which term a census was taken of the Roman population. A *generation* is the interval of time elapsed between the birth of a father and the birth of his son, and is generally used in computing considerable periods of time both in sacred and profane history. The interval of a generation is consequently of uncertain length, and depends on the standard of human life, and whether the generations are reckoned by eldest, middle, or youngest sons. Thirty years are usually allowed as the mean length of a generation, or three generations for every hundred years. A *reign* is the interval that elapses between the accession and demise of a monarch or supreme governor, and is a

term in frequent use by historians. It is a period, however, of very uncertain duration, and differs in different countries, according as the sovereign may be liable to assassination, deposition, and the like. Dr Hales has, however, shewn that the average standard of reigns is about twenty-three years, reckoning from a series of 454 kings in 10,105 years. A *century* (*centum*, a hundred) is a period of one hundred years, reckoning from the commencement of the first year in any given century; thus the current century is the nineteenth of the Christian era.

TABULAR CHRONOLOGY.

Under this head the leading events, phenomena, or facts recorded in history, are arranged in the order of time in which they have occurred—that is, in chronological order. When we look back, however, over the lapse of 3000 or 4000 years, and consider the imperfect modes of record, the changes and transcriptions through which these records have passed—or even the absence of all record, save undated monuments and vague tradition—it will not be surprising that the tabular arrangements of chronologists should be so frequently inaccurate and contradictory. A perfect tabular chronology is what mankind can now never hope to attain; a full record—even reckoning only such events as are of medium general interest—would be too vast either for compilation or perusal. All that we can reasonably hope to attain, is an approximation to the leading facts in the early history of our race, and a brief indication of the more important occurrences in later times. Referring the reader to the systematic chronologies of Newton, Blair, Playfair, Sir Harris Nicolas, and others, we shall merely remark, that the best mode of tabulating events is that which exhibits the dates in bold characters, and endeavours to arrange in juxtaposition the leading occurrences in the principal countries of the world. By these means, reference is greatly facilitated, and a notion of civil progress more intelligibly conveyed. Particular chronologies, as of meteorology, agriculture, ecclesiastical history, and the like, are most advantageously constructed in separate tables; that is, by tabulating, in consecutive order, the leading incidents in the progress of the individual science or subject. The language of tabular chronology should always be concise, elliptical rather than expletive—a mere indication rather than an account of the event recorded.

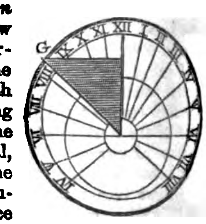
HOROLOGY.

Reference has already been made to the heavenly bodies and their motions as the most primitive and natural, as well as most perfect time-keepers. Our attention here, therefore, must be confined to those artificial machines which have been invented chiefly for the purpose of adding to the convenience of these, by dividing the unit of astronomical time-keeping—namely, the day—into fractional parts, such as hours, minutes, and seconds; there being no such convenient and desirable measurement obvious in nature. The science which explains the methods of so measuring and marking the fractional parts of the day is termed *horology*, from two Greek words, signifying *hour* and *discourse*—a term comprehensive of every time-keeping contrivance, from the simplest sand-glass to the most perfect chronometer. The instruments to which we shall here advert are dials, depending upon the shifting shadow of an object illuminated by the sun; clepsydræ, depending upon the equable flow of a liquid; and clocks and watches,* whose movements are determined by weights and springs.

* Although modern machines for measuring time are designated by the general appellation of clocks and watches, they are also distinguished by peculiar names arising from certain modifications in their construction, or from certain particular purposes they are intended to serve. By the term *clock* is understood an instrument which not only shews, but also strikes the hours; a *time-piece* is one which shews the hours without striking them; a *quarter-clock* is one which strikes the quarters as well as the hours; an *astronomical clock* is one which shews sidereal time; a *watch* is a portable or pocket time-piece; a *repeater* is one having a contrivance, by means of which it can be made to repeat the hours; a *chronometer* is a watch of the best kind, or one fit to be employed for astronomical purposes.—*Brande's Dictionary of Science.*

SUN-DIALS.

Long before the invention of any artificial time-keeper, the interval between sunrise and sunset was really divided, with no little accuracy, even amongst the rudest nations, simply by the shortening, turning, and lengthening of the shadows of trees, rocks, and mountains; and it was this primitive mode of dividing the day which no doubt naturally suggested the first idea of sun-dials. The earliest time-measurer of this description of which we have any historical notice, is the dial of King Ahaz, who lived about 742 years before the birth of Christ. According to Herodotus, the Greeks learned the use of them from the Chaldeans, probably through the Babylonian priest and astronomer Berosus, who taught and expounded in Athens about 540 years before Christ. Mention is made of the hemisphere or dial of this philosopher; and the octagonal Temple of the Winds, which is still standing, shews on each side the lines of a vertical dial, and the centres where the gnomons were placed. In Rome, sun-dials were not known till 293 B.C., when one was erected near the Temple of Quirinus—the rising and setting of the great luminary being the only standards of reckoning previous to this period. The Romans at this time were not aware that a dial made for Rome is not suited to other places. The ancients used hemispherical dial-plates, and placed the radius, which throws the shade, in the direction of the north polar star. Subsequently, vertical plane dials came to be the usual form, as may be seen on the fronts and gables of many of our old mansions. At present, the most common construction is the horizontal dial, or that in which the plane of the dial-plate is parallel to the horizon. In this form the style or *gnomon* G, the edge of the shadow of which determines the hour-line, runs in the plane of the meridian—that is, due north and south; while its sloping edge forms an angle with the horizon, or plane of the dial, equal to the latitude of the place in which the instrument is situated, and hence parallel to the earth's axis.



Although a sun-dial may certainly be adjusted so as to point out the time of day within a few minutes, it is needless here to dwell further on the details of an instrument now of little use. The most perfect of sun-dials being only available in sunshine, and not at all through the night—in which, by the way, moon-dials were sometimes used—they were partly superseded, even at a very remote period, by

CLEPSYDRÆ AND SAND-GLASSES.

It has been thought that the regular motion of the dropping of water, and the simpler forms of clepsydræ, or water-clocks, were used for the measurement of time even previous to the invention of sun-dials. They certainly were known in very remote antiquity, and were then used in various parts of Asia and Europe; in China, India, Chaldea, Egypt, Italy, and Greece; into the last of which countries they were introduced by Plato. Julius Cæsar found them even in Britain. It was by

them that he discovered some of the nights to be shorter or longer in this country than in Italy, which is nearer the equator, or line of equal days and nights. The Romans themselves had clepsydræ 100 years before Cæsar's invasion; and it is supposed that the Phœnicians had introduced them into Britain through Cornwall, where they traded for tin. The clepsydra, invented by Ctesibius of Alexandria, 145 B.C., consisted of a jar containing water, which slowly escaped by a hole at the bottom, while the oar of a miniature boat on the surface, as it sank with the fall of the water, pointed out the hours, which were marked on the side of the jar. It is even alleged that toothed-wheels were applied to clepsydræ by Ctesibius. Such instruments, however, though brought to great perfection in the ninth and tenth centuries, and indeed still used in India, have never been made to measure time with great accuracy. The principal defect is the unequal dropping of the water, caused by the varying depth or weight of the liquid in the containing vessel, increase or decrease of temperature, and change of barometric pressure. Very ingenious attempts have been made to remedy this defect, but the greater complexity and delicacy thereby occasioned, render the instruments of very little practical value. As time-keepers, clepsydræ may therefore be considered as superseded by ordinary clocks and watches.

The running of fine well-dried sand through a tube, or from an orifice in a containing vessel, was another obvious species of regular motion, very analogous to the flowing or dropping of water. Accordingly, sand-glasses, still in use in this and other countries, were of very early invention. We have evidence of their employment in the East about a couple of centuries before the Christian era. Though now used only for rude and trivial purposes—the half-minute glass being still employed on ship-board, and the two and a half or three minute egg-glass by the housemaid—some centuries ago, in Western Europe, they were the almost universal measurers of brief intervals; and hence the numerous allusions of our poets, and the symbolical representations on our monuments and sculptures.

PLANETARIUMS OR ORRERIES.

It is rather a curious circumstance, that, long before the invention of clocks or watches, artificial machines were constructed, imitative of the motions of the sun, moon, and planets—the natural time-keepers.

Of the planetariums of modern times, the first in England was one made for Lord Orrery, whose name has since been given to such machines. The talented and self-taught astronomer, Ferguson, who was originally a poor Scottish herd-boy, made several orreries, and used chronometers to keep them in motion. But though the accuracy with which wheels and pinions can be made to represent different revolutions is beautifully illustrated by the best of these machines, they can give no just conception of the relative size, distance, or velocity of the planets, or hence of the periods of their revolution. 'As to getting correct notions on this subject (the magnitude and distances of the planets),' says Sir John Herschel, 'by drawing circles on paper, or, still worse, from those very childish toys called orreries, it is out of the question.' A verdict so decided, and from such a source, renders any attempt at description or illustration unmeaning and superfluous.

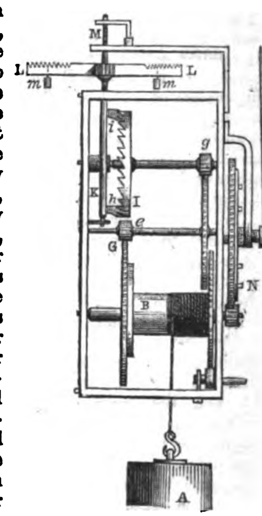
CLOCKS.

The strong hold which the planetary motions appear to have taken on the minds of our forefathers, as the great antitypes of all true time-keepers, is also curiously manifested in the fact, that even when a more detailed measurement of time became necessary, in the intellectual progress of nations, these motions still continued to be represented, so that the very first clock of which we have any perfectly authentic account—that, namely, invented by Wallingford, abbot of St Albans, in 1326—not only shewed the hours, but the apparent motion of the sun, the changes of the moon, the ebb and flow of the tides, &c. This, however, was by no means the first clock ever constructed; instruments with weights, wheels, pinions, and a balance, for the measurement of time, having been long previously known, though by whom invented, appears to be a subject of much controversy. Doubtless, they required more than the intellect of a single mind. Be this as it may, the most ancient clock of which we have any description is that of Henry Vic or De Wyck, a German, erected in the tower of the palace of Charles V., king of France, in 1379; and rude and imperfect as it was, the analogy of modern invention, especially in watches, would lead us to think that it must have been the fruit of several centuries of thought and improvement.

A portrait of this parent of modern time-keepers may be interesting to our readers; and, from its comparative simplicity, will be well adapted as a groundwork for further explanation of the mechanism of clocks and watches in their more complex and intricate forms. It will, moreover, shew the general mode of construction adopted in the fourteenth century, including the balance with weights, by which the motion was then regulated, instead of as now by a pendulum.

General Movement and Regulation of Clock-work.

Without requiring to enter into any very minute detail of the manner in which motion in a clock or watch is successively communicated from one toothed-wheel G or I, or pinion *e* or *g*, to another, which, indeed, would in some instances only tend to perplex the mind of the general reader, it will be readily understood that the weight A below the clock-work, wound up by a cord on the cylinder B, in its constant tendency to fall to the ground, will cause the cylinder to turn round on its axis as it falls, and as the cord uncoils; and thus one toothed wheel or pinion will set another in motion, till the movement be communicated to the crown-wheel, escapement-wheel, or wheel of rencounter (I), the teeth of which so act on the two small levers or pallets (*i*, *h*) projecting from, and forming part of, the suspended upright spindle or vertical axis (KM), on which is fixed the regulator or balance (LL), that an alternating or vibratory instead of a circular motion of the balance itself will be the result. The rotatory motion of the wheel-work, in short, will be converted into a vibratory motion by the alternate catching of the levers by the teeth of the crown or escapement wheel, and their alternate escape from them.



De Wyck's Clock.

Now, it will at once appear manifest that a heavy weight, such as that here represented, operating on a few wheels thus arranged, unless it have some counteractive weight, or other check, to modify and balance its operation, will rapidly run down even to the ground, if the height of the clock-work and the length of the cord attached to the cylinder permit it, causing the wheels to rotate, the balance to vibrate, and the hands to revolve

on the face of the clock, with similar rapidity, increasing every moment, till the weight be fairly run down. It is this rapid motion of the wheel-work which begins in a *modern* clock whenever the *pendulum* is taken away, while the weights are still attached to the cylinders; and the rapid ticking then heard is the uncounteracted operation of the crown-wheel, moved by the falling weight upon a piece of mechanism similar in purpose to the levers and spindle in the above figure. To prevent this rapid unwinding of the clock-work, then, and to adjust it to the more deliberate measurement of time, we have, in De Wyck's clock, the balance, *loaded with two weights* (*m*, *m*); and the further these are removed from the axis or spindle (KM), the more heavily will they resist and counteract the escapement of the levers and the rapidity of the rotation of the escapement-wheel, till the clock be brought to go neither too quick nor too slow.

Pendulum and Escapement.

What the balance and the weights attached to it in De Wyck's clock were to clocks of an ancient date, the pendulum is, in general, to modern clocks; the oscillations of the pendulum, and the vibrations of the balance, being completely analogous in purpose and effect, both being kept up or sustained by the 'escapement,' while both require, or, as it were, demand, by the law of gravity, a certain time for their performance; and thus, by reaction, check and equalise the exercise of those very powers and movements by which they are kept in play. The measurement of time being thus regulated by the oscillations of the balance or the pendulum, this part of the mechanism of a clock, including the escapement, is of primary interest and importance; and we shall find this also to be the case in the numerous contrivances, chiefly by English artists, to effect the same object to the best advantage in the still more delicate and ingenious mechanism of watches. We may here also remark, that so invaluable is the principle of *regulation*, whether by oscillation or rotation, and so generally and extensively useful in other respects, that from the smoke-jack to the steam-engine it has, in one form or other, been called into practical operation.

Galileo, the great astronomer, when a student at Pisa, happened to discover while engaged in the cathedral there—not in meditating on the imposing ceremonial of the Catholic Church, which was then in progress, but in what, to many a good Catholic, would undoubtedly have seemed the vacant, idle, and profane contemplation of the lamps which swung from the roof—that the oscillations of a pendulum, whether great or small, are performed in equal times in each pendulum—an important fact, the truth of which he tested, not by the beats of his watch (for no such instrument then existed), but by the beats of a natural time-keeper to which we have not yet alluded—namely, the pulse. He afterwards discovered what was ultimately demonstrated by Newton—that 'the shorter the pendulum, the less is the time of its vibration;' or, in other words, that the number of oscillations performed by a pendulum in a given time depends on its length—four times the length producing twice the number of oscillations. A pendulum, the length of which, from the point of suspension to the centre of the weight attached to its lower extremity, is 39 inches 2 tenths, will oscillate once precisely every second in the latitude of London; not in any other latitude, however, as has been found by experience; the number of oscillations with the same length of pendulum diminishing towards the equator, where oscillations equal in length to 2 minutes 15 seconds a day will be lost; while, on the other hand, they will increase towards the poles, where a proportional number of oscillations will be gained. Thus, as already explained under the LAWS OF MATTER, the pendulum of a clock, made and adjusted to time in London, requires to be lengthened if taken nearer to the poles, or shortened if taken towards the equator. The greatest possible nicety, indeed, is required in the adjustment of the length; for a difference, if in extent amounting to the 1000th part of an inch, would cause an error of about one second a day; therefore to make a pendulum go slower by one second a day, it must be lengthened by the 1000th part of an inch; and to make it go quicker, it must be shortened in the same proportion. The following are the results of some measurements of the seconds' pendulum at different latitudes in the northern hemisphere :—

Spitzbergen,	79°	49′	58″	N. Lat., . .	39·2146 inches.
Edinburgh,	55	58	40	" , .	39·1554 "
London,	51	31	08	" , . .	39·1390 "
Jamaica,	17	56	07	" , .	39·0350 "
Sierra Leone,	8	29	28	" , . .	39·0195 "

The first use which Galileo, then a medical student, made of his valuable discovery, was to ascertain the rate and variations of the pulse; and its application to clock-work was an after-thought. It is even denied that he did more than suggest such an application; or, as has been also alleged, that at all events his son put his suggestion into execution; and accordingly the merit of the invention of pendulum-clocks is very generally attributed to Hüygens, a learned Dutchman, about 1657. This celebrated philosopher, in adapting the pendulum to the mechanism previously invented, had little more to do than simply to add a new wheel to the movement, so as to enable him to place the crown-wheel and spindle in a horizontal instead of a perpendicular position, that the lower arm of the balance—then of course perpendicular, instead of horizontal, as in De Wyck's clock—might be extended, as it were, downwards, and thus, in fact, be converted into a pendulum. The principle thus adopted, however, from the peculiar action of the levers and spindle, required a light pendulum and great arcs of oscillation; and the consequence was, as has been remarked, that 'Hüygens's clock governed the pendulum, whereas the pendulum ought to govern the clock.' About ten years afterwards, the celebrated Dr Hooke invented a better method, which was introduced by Clement, a London clockmaker, in 1680, and enabled a less maintaining power to carry a heavier pendulum, which also making smaller swings or arcs, was less resisted by the air, and therefore performed its motion with greater regularity. This was called the *anchor escapement*, and it is still in use, together with the practice to which it gave rise of suspending the pendulum by a thin flexible spring instead of a cord, which was liable to change its length by moisture; an evil, however, perhaps fully equalled by the variation of the elasticity of the spring by heat and cold. The seconds' pendulum, with the anchor escapement, was called the *royal* pendulum. As this plan, however, was found to cause a reaction or retrograde movement of the wheels, and has hence been called the *recoil* escapement, a further improvement was made about the beginning of the eighteenth century by George Graham, another English artist, who invented the repose or *dead* escapement.

The wheels are kept by this escapement in a state of repose or rest during the whole oscillation of the pendulum, except at the moment when it receives its impulse from the crown-wheel. Requiring smaller arcs, too, even than before, the oscillations are made in more equal times. A still more perfect modification of the escapement is the free or *detached*, but it is more difficult to execute. The *half-dead* escapement, also, has been introduced as a mean between the dead escapement—an increase of power with which causes a clock to lose time

—and the recoil escapement, with which a similar increase of power causes one to gain. For the purposes of ordinary clocks, this mode of escapement has been found to answer very well.

In the great clock constructing for the new Houses of Parliament at Westminster, the pendulum is upwards of thirteen feet long, to beat two seconds, and its bob weighs six hundredweights. For keeping up the movement, a new contrivance, called the *gravity escapement*, is applied. It is thus described: 'The attempt has been made to give the push by the agency of a power that is, on account of its own intrinsic nature, absolutely unvarying. On each side of the pendulum-rod, a sort of small metallic hammer is hung upon a peg. The swinging of the pendulum first draws out a little bolt, that stopped the turning of a wheel; the wheel then goes round, under the influence of the weight, lifting one of the little hammers, as it does so, until it is caught by another bolt. The hammer-head next falls by its own gravity, and strikes the pendulum-rod just as it is in the act of descending, communicating the force of its blow to quicken the movement; the same thing is afterwards repeated on the opposite side of the vibration, and then again on the same side; so going on alternately. But the blow that is given to the pendulum depends upon nothing but the force of the hammer, which is lifted up by the train of wheel-work, and then descends with a strength that is exactly proportioned to its weight; but as this weight does not vary by the fraction of a grain, the blow never alters; its push is unchanging, and always the same in amount. The wheel has three stops and cogs on it, and goes once round in three beats of the pendulum, or in six seconds. . . . . This beautiful contrivance—now technically known as the gravity escapement—is of the highest importance in the practical applications of the science of horology; for it is found that when it is employed, all the teeth of the several wheels may be rough, just as turned out from the casting, and the clock will nevertheless keep better time than it would have done with the most perfectly finished teeth under other arrangements.'

Compensation Pendulums.
